LIST OF CONTRIBUTORS TO VOL. XXIX.

Abbe, Dr. Robert, New York.
Ambrook, Dr. Charles, Boulder, Col.
Arthur, Dr. George, New York.

Bacon, Dr. Charles A., New York.
Ball, Dr. A. Brayton, New York.
Barnes, Dr. W. Rounds, Binghamton, N. Y.
Baruch, Dr. Simon, New York.
Bates, Dr. William H., New York.
Beach, Dr. Wooster, New York.
Beale, Dr. Albert C., Rock Island Arsenal, Ill.
Beemer, Dr. N. H., London, Ont.
Bettman, Dr. Jefferson, New York.
Billings, Dr. John S., Washington, D. C.
Billington, Dr. C. E., New York.
Boldt, Dr. H. J., New York.
Brickett, Dr. George E., Augusta, Me.
Brooks, Dr. F. D., Clayville, N. Y.
Brown, Dr. Dillon, New York.
Brown, Dr. Sanger, New York.
Bucklin, Dr. C. A., New York.
Bull, Dr. William T., New York.
Burchard, Dr. T. Herring, New York.
Burrall, Dr. F. A., New York.

Canfield, Dr. H. A., Gilmor, Pa.
Carpenter, Dr. Wesley M., New York.
Carroll, Dr. Alfred Ludlow, New Brighton, N. Y.
Chapin, Dr. Henry Dwight, New York.
Chace, Dr. H. P., Highland Falls, N. Y.
Chase, Dr. A. G., Millwood, Kan.
Cheatham, Dr. W. T., Henderson, N. C.
Cheesman, Dr. Hobart, New York.
Chisolm, Dr. Julian J., Baltimore, Md.
Cipperly, Dr. John H., Troy, N. Y.
Cobleigh, Dr. E. A., Athens, Tenn.
Coonley, Dr. E. D. Mariners' Harbor.
Corbett, Dr. William Thomas, Cleveland, O.
Crandall, Dr. F. M., New York.
Crook, Dr. James King, New York.
Currie, Dr. W. Austin, Boston, Mass.
Cutter, Dr. George R., Brooklyn, N. Y.

Dana, Dr. Charles L., New York.
Dawson, Dr. B. F., New York.
De Garmo, Dr. W. B., New York.
Delavan, Dr. D. Bryson, New York.
Derby, Dr. Richard H., New York.
Dessau, Dr. S. Henry, New York.
Devlin, Dr. Robert J., New York.
Dodge, Daniel Kilham, Esq., New York.
Dolan, Dr. Charles P., Waterville, Minn.
Duggan, Dr. J. R., Baltimore, Md.
Dulles, Dr. Charles W., Philadelphia, Pa.
Dumm, Dr. S. C., Columbus, O.

Eichberg, Dr. Joseph, Cincinnati, O.
Eldridge, Dr. Stuart, Yokohama, Japan.
Eliot, Dr. Llewellyn, Washington, D. C.
Elliot, Dr. George T., New York.

Manning, Dr. F. O., New York.
Manley, Dr. Thomas H., New York.

Says Velpeau, speaking of incised wounds in general: "In order to attain this end, we must give to the dressing more care and time than is ordinarily given to it; the section of the soft parts should be neat and regular; the integuments should fall without effort on the front part of the stump." . . . "All the arteries liable to bleed should be immediately tied or twisted; the sides of the wound, freed from foreign substances, should touch throughout their whole surface." . . . "The straps should do no more than preserve the coaptation, without pressing or exercising any drawing force." . . . "The suture should be added to them, or even preferred, if the skin is thin or tends to roll inward; the diseased parts should be afterward kept in the most perfect immobility, and the inflammation should be moderated by every possible means."

When speaking of amputations Velpeau repeats in effect the same instructions.

Most of these surgeons have referred in their writings to the necessity of waiting until the surface of the wounds becomes *glazed*, before closing them.

"After a time," says Bennett, "the surface is glazed, as it is called;" and it is at this period that he recommends the closure of the wound.

Says Pirrie: "All oozing having been completely arrested, foreign matter removed, and the surface having taken on a glazed appearance," we may proceed to close the wound.

Not a few of the most distinguished operators went much farther both in their teachings and practice.

Mr. Syme says wait six or eight hours before closing the wound.

Velpeau says that "in order to arrive with more certainty at this result, Parrish, in America, and also a great number of surgeons in England and Germany, and Dupuytren, in France, have established a precept not to dress recent wounds but after the lapse of some hours." Dr. Townsend, in a note to the American edition of Velpeau, says that Dr. Valentine Mott "approves very highly of leaving many wounds exposed for some time, even for an hour or more."

Of those mentioned above, Mr. Syme subsequently modified his opinion so much as to permit the dressing to be made at the same time as the amputation.

Even at a date much later than any writer which has been hitherto mentioned, Mr. Erichsen has said, "Hence in the dressing of surgical wounds, such as stumps after amputation, and in all cases in which it is advisable to attempt to procure union by adhesive inflammation, the cut surfaces should not be brought together for a few hours, until all oozing of blood has ceased and the fibrinous layer has been thrown out."

It needs to be said that, following the example of Mr. Syme, after a time most surgeons relinquished the practice of waiting several hours before closing the wound, both because of its inconvenience and because in most cases the glazed appearance was found to be present sufficiently early to enable them to do so without compromising the desired result.

Alanson, Syme, Liston, and probably all the systematic writers of this period, taught the necessity of not only stopping all bleeding, but also of providing for the escape of serum by suitable drainage. Mr. Syme, in 1825, wrote a paper in which he spoke of the flow of serum as "invariable," and of the absolute necessity, therefore, of providing for its escape.

Let us now inquire what were the results of this plan of treatment, which was substituted for the open treatment, and which found favor with so many—nearly all, indeed—of the most practical surgeons at the close of the last century and up to a late period during the present century.

Alanson declares that, under his improved treatment, of 35 cases of amputation of the leg and thigh, at the public hospital in Liverpool, he did not lose one, while of the preceding 46 amputations he had lost 10.

Mr. Liston, a pupil of Syme's, says, that of the last 20 cases of amputation of the thigh for chronic disease, which he had seen performed by Mr. Syme under this plan of treatment, not one died; and this although some of them seemed in a nearly hopeless condition at the time of the operation.

Of 92 soldiers treated in this manner on the field of battle by Percy, 86 were cured in twenty-six days; and of 70 cases thus treated by Lucas only 5 died.

It is true that Pelletan, who did not favor the practice of attempting union by adhesion, lost 5 out of 6 treated by himself; but it is sufficiently apparent that he had not complied with two of the most important conditions of success, when he declares that in all the fatal cases the autopsy showed the presence of blood, as well as of pus, between the surfaces of the wounds; and that in the only case in which recovery took place the accumulated pus forced off the adhesive straps. He had neither secured the bleeding vessels properly, nor provided for drainage.

What treatment, either ancient or modern, has presented a better record than this furnished by Alanson, Syme, Liston, Percy, Lucas, and, so far as we know, by the faithful disciples and distinguished advocates of their practice?

It is scarcely necessary to remind you that these results were obtained before the introduction of anæsthetics or of antiseptics.

In the face of these remarkable and universally conceded successes, which contrasted so strongly with the slow and uncertain results of the earlier practice, it is hard to understand how any steps backward could have been taken; but this is what actually happened, the retrograde movement commencing even before the distinguished advocates of the new system had died. Here we enter that point in the history of the treatment of wounds to which I have already referred, as that in which the practice of attempting to obtain union by adhesion "faltered," and surgeons were everywhere returning to the practice of leaving their large incised wounds to suppurate and granulate. Of the fact as now stated there is no question. How this change was brought about I will now attempt to explain, and also how, through the agency of one man, Mr. Lister, the practice of union by adhesion was happily restored.

In the first place, to comply with all the conditions demanded for union by adhesion requires time and painstaking. It demands scrupulous attention to the most minute details. To omit one of the many conditions named is, in most cases, as fatal as to omit the whole. Celerity is here inconsistent with success. Surgeons, therefore, who wish to acquire a reputation as "brilliant" operators, are likely, especially in their public or hospital exhibitions, where their example can do most harm, to fall short of the requisition, and then, by their failures, to bring discredit upon the system they teach and are attempting to follow.

Second, war is unfavorable to this department of surgery. The exigences of the battle-field do not supply the time, nor the appliances necessary for the application of all the principles involved in primary union. There are many occasions on the field of battle when the demands upon the surgeon to save the life of the patients temporarily, must be paramount to all other considerations, and in which, as Armand has said, the only precept is, *cite, citissime.*

Macleod says, speaking of his experience in the Crimean War, "I never saw one case among our most numerous amputations in which primary adhesions took place throughout the whole surface of the flaps."

My personal experience in our own late Civil War was that primary union after large amputations was the exception; and that toward the close of the war army surgeons were everywhere returning to the practice of open dressings. This lack of success in their attempts to secure primary union upon the field induced, it is fair to suppose, on the minds of many who did not sufficiently

consider the causes of their failures, a general lack of confidence in the plan, which led them to reject it even after they returned to civil practice.

If Percy had better success as an army surgeon in securing primary union than most other surgeons have had, it was because he was better able to comply with the conditions.

Third, the introduction of anæsthetics has had no inconsiderable influence. My own experience has not furnished me with any evidence that general anæsthesia has appreciably delayed the union of tegumentary wounds, or of the majority of small wounds, when they occur in most of the other tissues of the body. What the fact may be in this regard, I am unable to say, nor would it perhaps be very easy to determine; but in reference to its effect in large muscular wounds, or in major amputations, and especially where muscular flaps are made, I have no doubt their union has been thereby delayed and often prevented.

I practised surgery some years before the introduction of anæsthetics, and soon after I began to use them it became a matter of common observation with me, and of comment, that the same measures did not so often insure primary union as before. I think also that Macleod's experience in the Crimean War, already referred to, goes further than proving that amputations made under these circumstances do not usually comply with the conditions of success. He says that "chloroform was almost universally used in the British army." If, then, he was unable to meet with a single case of complete primary union, it seems fair to charge a part of this result to the general use of chloroform.

But aside of any specific testimony upon this subject, let me appeal to the reader's intelligent judgment. When large flap amputations are made while the patient is completely under the influence of an anæsthetic, in addition to the total loss of sensibility—for which both operator and patient have reason to be thankful—we observe that the muscles do not quiver and retract under the knife, that they hang apparently lifeless from the wound as they do when made upon the cadaver, and that they do not wholly resume their normal contractility and position until some hours after the operation is completed. The arterial blood is dark, and can scarcely be distinguished from the venous, showing that it is imperfectly oxidized. The surface of the wound has a dark, grumous look, wholly unlike the appearance presented under other circumstances.

Is it reasonable to suppose that the effusion of lymph, so as to give a glazed appearance to the wound, and which is essential to primary union, will not, under these circumstances, be delayed? and that this delay will not often extend beyond the period when primary union is possible? For myself, if I were asked this question, and no evidence were presented on either side, I would say it must necessarily be delayed.

I have been speaking thus far of the circumstances which seem to explain why surgeons for a while faltered in their faith in primary union. This explanation, however, which may or may not be correct, was not necessary to the historical sketch which I proposed to make. The material point is, that for a time surgeons did actually treat wounds as if they had forgotten the conditions of success, or had lost faith in the earlier teachings.

In attestation we have only need to recall what we have often witnessed in the public amphitheatres in this city and elsewhere during the last twenty or thirty years; large flap amputations, made dexterously, but afterward the surfaces of the wound rudely handled, fretted by rough sponges, the wounds closed before the blood had ceased to flow, then hermetically sealed by adhesive straps, without provision for drainage, and hurried from the amphitheatre to make way for another brilliant operation.

To one who has only observed the results of this method of treatment, without having given attention to the means by which they were brought about, the sole conclusion must be, that it would be far better to return to the old practice of leaving the wounds open, since nothing short of a miracle could secure primary union; and this is precisely the conclusion to which, within a few years, some surgeons have arrived.

We have now reached the period in the history of surgery when Mr. Lister interposed, and turned back the tide. He taught that under a most thorough system of antisepsis primary union could be secured; and he demonstrated that it could be secured even after the most profound anæsthesia. This was the great lesson which he had in his mind, and which he successfully taught; but he taught also, incidentally, that the wound must be handled gently, all foreign substances must be removed, the blood must cease to flow, and provision must be made for drainage. In short, if you will look carefully into his teachings and practice, and the practice of his disciples, you will see that they omit nothing which, in the opening of this paper, I declared essential to success; and I venture to say, that if they did, no amount or quality of antisepsis would secure union by adhesion.

The influence of Mr. Lister, backed by his specious theories, secured a return to the old practice of the advocates of primary union in all its essential details, and to this it added antisepsis. Fortunately, antisepsis carried with itself, inseparably, one thing more, namely, the agency of a moderate stimulant and astringent, which served materially to resuscitate the tissues and the capillary vessels which had been temporarily paralyzed by the general anæsthesia, and thus in some measure to counteract its deleterious effects.

As to his practice of removing carefully and effectually all foreign substances before closing the wound, and providing for the escape of the serum or blood which might subsequently be effused between the cut surfaces; and as to his practice of applying industriously, so long as the wound was open, a moderate stimulus to the cut surfaces in the form of spray or lavements of dilute carbolic acid—these are *facts* which admit of no dispute. But as to his declaration that the results which he obtained were due to the destruction of certain microorganisms constantly floating in the atmosphere, and which being received and propagated upon the raw surfaces prevent primary union, or which being conveyed into the system by absorption cause septicæmia—this is only a *theory*, and one which is far from being universally accepted. It has not been conclusively shown that the formation of pus depends in any case upon the presence of germs. When suppuration takes place in closed cavities these germs are generally absent; but as if to show how impossible it is to prevent their pernicious intrusion—in case it be admitted that they can or do cause suppuration—they are occasionally found in great numbers in cavities which have never been open to the air.

If germs are so readily absorbed by open surfaces, and distributed through the system, of what possible use is it to commence the application of the antiseptics one or several hours after the reception of a wound, or months after the skin has been destroyed, and then apply it with so much assiduity, so long as the knife of the surgeon or his hands are in the wound?

If, on the other hand, the germs are not so easily absorbed, and only nestle upon the surface of the wound, why, instead of using the antiseptic from the beginning to the close of a surgical operation, is it not sufficient to apply it thoroughly just before closing the wound?

There is one quality or property of antiseptics to which allusion has not yet been made, namely, their power to prevent the decomposition of blood, of pus, and of serum; the decomposition of either of which changes these otherwise comparatively innocuous fluids into an irritating ichor. But when employed for this purpose they can serve no useful end, except when blood, serum,

or pus are actually present. To apply them, therefore, immediately preceding the closure of the wound, and whenever subsequently blood, serum, or pus present themselves, or seem likely to present themselves, is rational, and would justify their employment also, within certain limitations, in all cases, after the closure of the wound and until the end of the treatment; but it supplies no argument for the adoption of all the complicated procedures with which Mr. Lister and his disciples preface and encumber their operations.

The conclusion to which we are brought is, that while we are indebted to Mr. Lister for having restored confidence in union by adhesion, it seems equally certain that his excellent results have been obtained, not by a literal compliance with the rules which are the logical deduction from his theories, but by his strict enforcement, in the practical application of his theories, of certain other conditions, which he seems to regard as accessory and incidental, rather than of paramount importance.

If this conclusion is correct, then there is not sufficient reason why the air of a room in a private house, or even in a public hospital, not suspected of being infected by some contagious or infectious disease, such as diphtheria, scarlatina, erysipelas, etc., should be disinfected before an operation is performed, or why all persons present should have been previously disinfected, or that they should be required to breathe through disinfecting respirators, or should wash their hands in carbolized water, or search beneath their nails for concealed germs, or why they should carbolize their instruments, or why, indeed, they should pour a constant stream of carbolized water or of spray upon the wound while operating, except, as I have already stated, for its utility in closing the capillary vessels, and its power in restoring tone to the paralyzed tissues when anæsthetics have been employed.

The various manipulations and devices for the purpose of excluding the germs above enumerated have at one time or another been suggested by Mr. Lister or his disciples, and, in my opinion, they are all necessary if Mr. Lister's theory be correct. If it be not correct, they serve no other purpose than do the walking, talking, and gestures of the prestidigitator. They abstract the attention, and conceal the adroit manipulation by which the trick is actually performed.

I say this with all respect for the integrity of the distinguished surgeons who hold strictly to Mr. Lister's opinion and practices, since in one particular they differ from the class to which I have compared them. The prestidigitators are not deceived, but deceive their audiences; while Mr. Lister and his disciples deceive both themselves and their audiences.

It will be observed that I have thus far spoken only of carbolic acid as an antiseptic, since it is that which was first used by Mr. Lister, and still continues to be more commonly used than any other; but I am aware that surgeons have lately substituted many other things for carbolic acid, and with equally satisfactory results; and that many who continue to prefer carbolic acid have rejected the continuous spraying, and in several other particulars have modified the treatment. At the present moment a weak solution of the bichloride of mercury is the most active contestant of the alleged superior virtues of carbolic acid.

In a paper read before the New York County Medical Association in February, 1885, Dr. Theodore R. Varick, surgeon to St. Francis' Hospital, Newark, N. J., states that he has for nearly six years substituted hot water, or water a little below the boiling-point. Immediately after the larger vessels have been tied, he applies the water freely and continuously to the raw surfaces until all oozing has ceased and "the parts are thoroughly glazed." The effect of this is, as claimed by Dr. Varick, to coagulate the albumin in the serum, by means of which the open vessels are closed against the admission of germs, and to impart a moderate stimulation.

In a private letter Dr. Varick informs me that of thirty-nine major amputations thus treated, mostly in cases of railroad accidents, only two terminated fatally, one by hemorrhage and one by cardiac disease; and that in all of the various operations performed by him there has been no case of septicæmia or of pyæmia, "although in several instances the hygienic surroundings have been of the worst kind."

Dr. Varick attributes his remarkable success, which is probably equal to that obtained by those who adhere to the use of carbolic acid, or of the bichloride of mercury, to the power of hot water to close hermetically the capillaries, and thus to prevent the admission of germs. Since, however, in most of his cases—railroad injuries—there must have been extensive exposure of the vessels by laceration, it is again difficult to understand, as I have before suggested, how they can be excluded when the door has been left open for some hours before the patients came under his notice. In short, while I fully approve his practice, and have myself often adopted it, I do not accept his theory.

Mr. Lawson Tait, in reporting "a series of one hundred and twelve consecutive cases of consecutive operations for ovarian and parovarian cystoma without a death," and in which no antiseptics were employed, says: "I tried the so-called antiseptic system in all its ever-varying details in as complete and unprejudiced a series of experiments as I believe it possible for man to undertake." . . . "I finally came to the conclusion that my patients were being poisoned by the use of carbolic acid, thymol, and various other substances, which were being used by others as well as myself for the purpose of destroying the germs which were supposed to do so much harm," . . . and he adds, that his experience had proven to his own satisfaction conclusively that he "could do better without Listerism than with it; that, in fact, the only tendency of this so-called antiseptic system was to mar" his success.

In the light of all that has already been said upon this subject no one familiar with Mr. Tait's careful and painstaking mode of operating, will fail to see where lies the real secret of his hitherto unparalleled success, and which he himself says is due to "increased personal experience, increased attention to all the minute details which go to create success, and inattention to any one of which may defeat the best-laid plans." "In every case," he adds, "where there has been a tendency to ooze, or where the patient has been advanced in life, I have used the drainage-tube, an addition to our means of saving life of which it is impossible to speak too highly."

I agree fully with Mr. Tait, that this simple narrative of his personal experience, the accuracy of which is assured by his acknowledged integrity, and by abundant collateral testimony, ought to "dispose forever of the much-discussed question of Listerism in abdominal surgery"

Incidentally I will add that it ought to furnish a beam of light to those surgeons who, during the last three or four years—ever since the death of President Garfield—have been prophesying the brilliant future of gunshot wounds of the belly under a "strictly antiseptic treatment," according to whom the time was near, if it had not actually arrived, when, under the protective influence of antisepsis, surgeons would open the belly freely, unravel the intestines and close their wounds, search carefully through every pocket of the peritoneal cavity, and, if need be, dissect and explore the regions outside of the peritoneum, and, having found and removed the lost ball, they would wash out the fecal matter and the blood which had necessarily escaped into the peritoneal cavity, and close the abdominal wounds, with a reasonable probability of restoring the patient to life and health. The fact that the vertebræ had been penetrated and were crumbling would constitute no bar to success; and indeed nothing would interpose a serious obstacle, except that the missile had lacerated some important blood vessel, or had buried itself in some solid viscus, a fact

which perhaps nothing but an ante-mortem or post-mortem dissection could determine.

These inspired revelations, uttered sometimes with a certain tone of regret for the lamentable ignorance of those who have lived before them—generally by men who have had little or no personal experience in the treatment of such wounds, and who certainly never practised successfully what they foresaw in their prophetic vision—still wait for fulfilment, notwithstanding the many thousand opportunities which both civil and military experience have since furnished.

I am not prepared to say that surgeons have not exaggerated sometimes the dangers and difficulties of searching for balls which have entered the cavity of the belly; but I do not think so; and I believe that all surgeons who have had much experience in this class of injuries will agree with me. I only intend to say that antisepsis has in no degree abated these dangers and difficulties.

Before dismissing this subject it seems necessary to consider briefly certain relatively modern suggestions, other than antisepsis, which have been made for the purpose of securing the primary union of large incised wounds.

"Bruising" the vessels, first suggested by M. Briot, and "torsion," which owes its introduction to M. Velpeau, are both still practised upon the small vessels with a certain degree of success, but in my personal experience both have more often failed.

Veitch, in 1806, used for the ligation of both large and small vessels very fine silk, and cut off the ends, leaving the knot in the wound to become encysted; but as small abscesses subsequently formed in many cases, Ruysch, of Germany, and Physic, of this country, substituted animal ligatures, and treated them in the same manner. Valentine Mott says, like the silk ligatures they often formed abscesses, and after a short time their use was almost entirely abandoned.

At the present time we see the practice of using the animal ligature revived, but only, for the most part, in its application to small vessels upon the surface of the wound. In this manner they are now used quite freely, and no doubt serve the purpose of shortening the period we may have to wait before closing the wound, and of giving additional security against secondary hemorrhage during the early period of reaction. Notwithstanding the statements made to me by some surgeons, that they have seen no abscesses follow their use, this has not been my experience. In at least two cases out of the few in which I have adopted this practice very small abscesses have formed. I must, therefore, consider the method as still under trial.

The substitution of cloth or a towel for the sponge, as a means of removing the blood from the surface of the wound, made, as I understand, for the purpose of protecting the patient against septic germs, is subject to the criticism that it is illogical. If germs can be destroyed which lie exposed upon the surface of a wound, or upon instruments, they can equally be destroyed when they lie secreted in sponges, by a thorough saturation with some disinfectant, or by boiling water; and if they cannot be so disinfected, neither can the towel be. I observe, however, that in using the towel it is only laid upon the surface, not drawn roughly over it, and in this practice I see a positive gain. When a sponge is drawn roughly over the quick and sensitive wound, in the case of a patient who is not anæsthetized, it causes most acute pain; and although when the patient is insensible it can no longer cause pain, it can fret and partially disintegrate the surface as when rasped by a file. If surgeons' assistants cannot learn how properly to use a sponge, let them use a towel.

Drainage-tubes made of bone, from which the mineral structure has been removed, and which, therefore, may become dissolved or even absorbed, present no possible advantage over the ordinary india-rubber flexible tube, except that, if by any accident they should escape into the wound, they will take care of themselves and probably do no harm. The objection to them is, that they are short and inflexible, and cannot be made to follow a long and tortuous canal.

In closing the wound some modern surgeons have given the preference to metallic sutures, others to the animal sutures, or to horsehair, for each of which it is claimed that they cause less irritation than silk, and in this way improve the chances of primary union.

Any suture, no matter of what material composed, will cause irritation and suppuration at the points of pressure, if it is employed upon tegumentary tissues for the purpose of drawing the lips of the wound together forcibly, as when, owing to a deficiency of structure, they could not otherwise be made to meet; but I have elsewhere explained that this is not, in tegumentary wounds, and but rarely in any wound, the proper function of a suture.

In the class of cases now under consideration, where we desire prompt primary union, the suture is intended only to place the edges of the wound in accurate apposition, and to prevent inversion. For this purpose the finest silk suture, introduced as near the margin of the wound as possible, and tied lightly, is the best. It will cause no more irritation than the wire or horsehair, is much more flexible and adjustable, and is, therefore, much more easily and painlessly introduced and removed. The accuracy of these statements I have frequently verified by employing the two materials on different parts of the same wound.

The value of the animal suture consists solely in its being spontaneously removed. If it be claimed that its value, as now generally employed, consists in its being carbolized, the reply is, that the silk may be treated in the same way. The only objection which I have to its use is, that it is less flexible that silk and is not so fine as the finest silk.

Hot water, as a means of imparting a healthy stimulus to paralyzed tissues, of arresting capillary hemorrhage, and of removing the blood from the surface of the wound, has long been employed by me, applied by means of a sponge. The suggestion of Dr. Varick, to apply it in an interrupted stream from the nozzle of a pipe connected with a reservoir, in the same manner in which the antiseptic solutions are now often employed, commends itself theoretically and by its results. A current of hot water, falling with moderate force upon the wound, not only removes the blood from the surface, but also washes it from the tissues where it has accumulated around the bleeding orifices of the small vessels, exposes them to view, and enables the surgeon to apply a ligature if required. It also coagulates the albumin, and for this reason, if for no other, it ought to be satisfactory to those who believe that by the interposition of this shield the vessels are protected from the intrusion of germs; while it is absolutely innocuous, a quality which is not possessed by any of the antiseptics, so called, now in use. The occasional toxic effects of carbolic acid and of the bichloride of mercury, in their surgical application, are known and admitted by all the advocates of antisepsis.

Dr. Varick recommends that the water have a temperature "slightly below the boiling-point." This might do if one were to apply it by means of a sponge, and then only for an instant, as I have often done to close a bleeding arteriole; but if employed continuously, or by irrigation, through the nozzle of a tube, it ought not to exceed in temperature 112° or 115° Fahrenheit, or the temperature which may be easily borne by the naked hand.

Finally, I wish to say that while it seems to me capable of demonstration that the real secret of Mr. Lister has lain concealed under a series of complicated manipulations, my confidence in the intelligence of my professional brethren is such that I believe they will soon abandon all those procedures which are irrelevant and wholly unnecessary to success. This is what they have already begun to do. In addition to those whose names I have mentioned, Mr. Keith, Mr. Callender, Mr. Savory,

and Mr. Bryant, have publicly declared their non-acceptance of the doctrines of Mr. Lister, as have also a considerable number of equally distinguished French and German surgeons; and the number of those who have, after a fair trial, substantially ceased to practise them according to his theory, is constantly increasing. Let us take care, however, that in severing our attachment to certain theories and practices, we do not loose our hold upon anything, whether new or old, which is really useful.

Antiseptics have their position and function in a great variety of wounds, including large simple incised wounds, under certain circumstances, and at certain stages of their progress. What this position is in the latter class of cases—whether it be dominant or subordinate—I have sought to explain.

EXTRA-UTERINE PREGNANCY—A NEW DIAGNOSTIC SYMPTOM OF RUPTURE.

By J. J. E. MAHER, M.D.,

NEW YORK.

On September 15, 1885, I met in my practice with a case of sudden death from an obscure cause. The patient was a lady, aged thirty-two years, a blonde, five feet three inches in height, and weighed one hundred and twenty pounds. She possessed a good physique, powerful endurance, and rather neurotic temperament. She had been a book-folder for five years previous to December, 1884, when she became a sewing-machine operator. In the latter capacity she labored till April 15, 1885. Her family history presents nothing of hereditary influences.

She began to menstruate at the age of fourteen years. No unusual disturbance became manifest in connection with the establishment of this function, nor did it at any time suffer any derangement till interrupted by pregnancy, at the age of twenty years. At full term she gave birth to a healthy male child, and made a good recovery.

Two years later, when near the end of another pregnancy, she received a blow on the abdomen from her husband, and was confined to bed for several days on account of it. In due time, however, a healthy female child was born after an easy labor. Her convalescence seems to have been somewhat protracted. As a sequel of this gestation, she suffered every month thereafter from dysmenorrhœa. In the intervals between these periodical attacks of suffering and malaise she enjoyed good health, and continued to do so till July, 1884, when after a fall on the pavement she suffered from contusion of the right hip. This, however, passed off in a few days, and left her in her usual health. I might here remark that she had separated from her husband, and during the two last years of her life cohabited clandestinely with another man.

About March 1st she became enciente, and six weeks afterward terminated her pregnancy by a provoked abortion. The consequent illness is not said to have been severe, for she rapidly retrieved her lost health and spirits, and in a very few days was enabled to participate in various active amusements. Toward the end of May she began to complain of some slight pain in the lower abdomen, and every now and then she would observe that it was increasing in severity. On June 27th she was completely prostrated by abdominal cramps, and obliged to remain in bed on account of her sufferings for four days. In a few days she was approximately well again (so far as the pain was concerned), and indulged in severe exertion with seeming impunity. About August 1st her menses, which hitherto had been regular, ceased, and appeared no more. This was her own statement, but I am forced to doubt the verity of it, by certain collateral evidence which goes to prove she suffered from metrotaxis up to a few days before her death. About two weeks after this, the abdominal pain, which had gradually become troublesome again, now suddenly assumed a different character, and much resembled that of her dysmenorrhœa. This led her to believe her menses were about to reappear, but in this she was deceived. About this time rectal and vesical tenesmus was superadded, while at the same time she began to suffer from constipation, restlessness and insomnia. For this condition she sought medical relief about September 1st, and learned from her physician that she was suffering from inflammation of the bowels.

On September 15th, about 8 A.M., when attempting to rise, she fell back, prostrated by the sudden aggravation of the abdominal pain. She compared this pain to that of a knife driven into her side. Flexion of the thighs seemed to relieve her somewhat, and hence she assumed a sitting posture, which she maintained for about ten minutes. Being forced to lie down because of a feeling of faintness, she tossed about, endeavoring to assume a decubitus that would afford any respite from the excruciating pain. At 11 A.M. she fainted, and remained syncopated about fifteen seconds, during which a well-marked convulsion was observed. Four times during the afternoon these evanescent fainting attacks recurred, but without convulsions.

About 1 A.M. I was called to the bedside. I found her lying in the left lateral position, with the shoulders depressed, and the knees drawn up, as if endeavoring to relax the abdominal wall. Her countenance, expressive of intense suffering, presented an astonishing pallor. The skin was cold and covered with clammy moisture. Her hands and feet were fast becoming numb. In this frigid state the abdomen was remarkably hot. It was greatly distended, and so painful that the slightest touch could hardly be tolerated. She complained of heat in the stomach and an insatiable thirst, and craved cold drinks. Every draught of whiskey-and-water induced vomiting. Her bowels were confined. The pulse was rapid and thready; the temperature in the mouth 93° F.; the respirations accelerated, shallow, and at intervals interrupted by a yawn or sigh. She was weak, somnolent, and unwilling to be disturbed. When spoken to, however, she was easily aroused, and answered questions in a tone of voice at first enforced by excitement, but almost instantly subdued by exhaustion. Having about finished her reply, she would relapse into her previous lethargic condition. There was no evidence of external hemorrhage. She said she felt pregnant six weeks, yet no external palpable evidence could be found to corroborate her statement, nor did she experience any of those subjective symptoms she was wont to have in connection with her former pregnancies. Vaginal examination, however, showed the os uteri to be patent, the cervical canal admitting index finger to the extent of the first phalanx; the cervix soft, displaced forward, and fixed behind os pubis. The extreme tenderness of the abdomen prevented all further physical exploration.

From the foregoing symptoms was deduced a diagnosis of abdominal hemorrhage with collapse. Heat was applied externally and whiskey administered. My hypodermic syringe not being available, suppositories of one-quarter grain of morphia were ordered. Immediately after the insertion of a single suppository, a tonic convulsion supervened and continued about half a minute. Then, with a precipitant movement of the body, she rolled on her back. She was now unconscious, and could not be aroused. The radial pulse had disappeared, the heart's action was inappreciable, the respirations rapidly became slower and fewer, and in two or three minutes death closed the scene.

At the autopsy, shortly after death, the abdominal incision made along the linea alba, down to the peritoneum, was bloodless. On opening the peritoneal cavity a huge mass of coagulated blood was exposed. The removal of this discovered a fœtus presenting at the abdominal aperture. The cord was still intact, and was traced to a cyst situated on the right side of the pelvic cavity. This was firmly adherent to the peritoneum of the right lateral and posterior walls of the pelvis, and on the left side to the rectum. The rest of the intestines,

matted together by clotted blood, were entirely free from any adhesion. A collection of serous fluid was found in the right flank. No other morbid changes were observed.

The fœtus was five inches long. The head, somewhat large, was well shaped. The cranium, soft as a bag of fluid, presented ossific plates on the parietal, frontal, and occipital protuberance. The eyelids were adherent; the male genitals quite distinct; and the nails well defined. This is obviously a description of a four months' fœtus. The cord, five and a half inches long, was attached to the left margin of the placenta.

The cyst was situated behind and to the right side of the uterus. It was adherent, on the right side, to the pelvic peritoneum as above stated; on the left, to the rectum, to the extent of four inches of its length and one-third of its circumference. The walls of the cyst varied in thickness from one to five lines. The rupture, nearly three inches long, took place, from before backward, along the attachment of the rectum. The placenta was situated on the anterior wall of the sac, and, at the time of rupture, was detached from its bed to the extent of one and a half inch.

The uterine walls were thickened. The cavity, measuring three and a half inches in length, was lined with a shaggy decidua, while the cervical portion was filled with a gelatinous mucous plug. The left tube was pervious. No corpus luteum was found in the left ovary. The right tube would not admit the smallest probe. The right ligament was not dissected.

From the relation of the parts involved, if a communication were to have been established between the fœtal sac and any of the hollow viscera, it would most probably have been with the rectum. Hence this case would have proved an exception to the rule observed by Tait, who says, "If on the right side it evacuates into the cæcum."

That the diagnosis of extra-uterine pregnancy is always difficult, and often impossible, the literature of the past affirms, and that of the present does not seem to contradict. Dr. Thomas, who has reported some thirty cases (the largest number recorded by any one man), after relating his experience in twenty-one cases,[1] drew the following diagnostic conclusions, which may be thus summarized: Symptoms of normal pregnancy accompanied by (1) irregular gushes of blood, ceasing and suddenly recurring without any assignable cause; (2) fixed grinding pain in one iliac fossa, and perhaps down the thigh on the same side; (3) paroxysms of severe pain, with constitutional symptoms, passing off in a short time, to recur in a few days with increased violence; (4) symptoms of abortion without the appearance of a fœtus; (5) expulsion of membranes without accompanying fœtus. Physical signs: (1) Increased size and displacement of uterus; (2) evidence of vacuity of uterine cavity; (3) presence of a cystic tumor, painful to touch, rather immovable, with obscure fluctuation, and sometimes ballottement. Dr. Goodell, following Thomas on the occasion, added,[2] "If after a long sterility a woman become pregnant, suspect extra-uterine fœtation;" and, "The forward displacement of the cervix and bulge in Douglas' pouch often mimic retroflexion of a gravid uterus;" and also, "The supposed uterine globe is smaller than at that time in normal pregnancy." As these symptoms have no particular reference to rupture, Parry adds[3] at this time: "A sudden accession of pain in one iliac fossa with metrorrhagia; a feeling as if something had torn inside of her; symptoms of shock accompanied by great weakness; convulsions and delirium, or perfectly clear intellect; and the abdomen becoming suddenly very severely painful, distended, and dull on percussion; and 'if metrorrhagia has not preceded the symptoms of rupture, it quickly follows them in almost all instances.'"

The above enumeration is unquestionably a faithful picture of a typical case. Thomas says,[1] however, "It is much easier in the lecture-room or in a written treatise to lay down distinctions in these cases than at the bedside." "In all cases of difficult diagnosis," says Matthews Duncan, "if you do not suspect a thing, you are almost certain not to find it."

As there is as yet no symptom known that can be considered peculiar to extra-uterine gestation, and as all the symptoms can do no more than arouse a suspicion of that condition, to be rendered positive or negative by physical signs, so even to suspect extra-uterine fœtation it is absolutely necessary to have suspicious symptoms. Of the five symptoms of Dr. Thomas three refer to the metrorrhagic discharges, and are alone suspicious. The long period of sterility is said to be suspicious. In the foregoing enumeration there are, therefore, only four suspicious symptoms, and of these only one, the feigned sterility of nine years, was present in my case; but before any importance can be attached to this symptom as suspicious of eratic gestation, it must first be proven that the woman is pregnant. Since there was no positive evidence of pregnancy, even the previous sterility lost its value as a suspicious symptom. There was not in my case, *à priori*, a single symptom that could lead a medical attendant even to suspect the existence of extra-uterine pregnancy antecedent to an autopsical revelation.

Fränkel[2] will accept no symptom unless pregnancy has so far progressed that its existence can be proven beyond a doubt, and the uterus is empty.

Vulliet showed his honesty when he reported[3] the case that had been four months in his private hospital, and had been examined many, many times during that period, but was not diagnosed as one of extra-uterine pregnancy until the abdomen was opened. If, with plenty of time, every convenience and facility, Vulliet could not diagnose his case of tubovarian gestation, it becomes difficult to understand how in many of the recorded cases the vaunted diagnosis had been made *ante-mortem*, with such marvellous precision.

Parry, treating of rupture, asserts[4] that "the symptoms of this are well marked." The above symptoms, however, taken from his work, presuppose a diagnosis of the real condition, and consequently if there be no such presupposed knowledge, these well-marked symptoms are not in the least peculiar to rupture of an extra-uterine fœtal cyst. This becomes obvious when it is remembered that the fourth case in Tait's series,[5] operated upon at the time of rupture, was diagnosed by him as one of pyosalpinx. Paul Mundé has recorded a case[6] of tubal pregnancy, the diagnosis of which, made by him, to "make assurance doubly sure," was corroborated by Emmet, and in which, after the application of twenty-four volts of galvanism, all the above-marked symptoms supervened, the weakness being in a small degree. So positive was he that rupture had taken place, that he was waiting only for the patient to rally to perform laparotomy. Though the requisite diagnosis had been made before their onset, time proved those marked symptoms to be due to nothing more than purely nervous shock.

Speaking of this difficulty in diagnosis at the time of rupture, Tait[7] says: "As I have now completely adopted the principle of always opening the abdomen when I find a patient in danger with abdominal symptoms, this barrier no longer exists."

From a therapeutical standpoint, the great desideratum in diagnosis is undoubtedly to establish, if possible, the existence or absence of abdominal hemorrhage. The afore-cited case of Mundé shows the almost insuperable difficulty. Treating of laparotomy after rupture, Lusk[8] quotes Kiwisch, in recommending the operation, as hav-

[1] Transactions of American Gynecological Society, [illegible]. Tait
[2] Extra-uterine Pregnancy, p. [illegible]

[illegible]

ing advised to make a small puncture through the peritoneum, and to introduce a pipette into the abdominal cavity, "in order to be sure that internal hemorrhage had really taken place." But this pipette exploration would have been of doubtful expedience in Clark's[1] case, where it is reported that the liquor amnii was the first thing to issue from the abdominal opening at the autopsy.

It was observed that a diagnosis of abdominal hemorrhage had been presumed in my case. It was founded on the following evidences: The symptoms of shock, accompanied by great weakness; the sudden onset of severe pain in, and distention of, the abdomen, and that remarkable abdominal heat, both subjective and objective, presenting so striking a contrast to that of the rest of the body.

This symptomatic abdominal heat does not appear to have hitherto attracted any attention in the cases already recorded; yet if it be remembered that there is beneath the abdominal wall a clot of warm blood varying in bulk from one or two quarts to as many gallons,[2] it becomes an easy matter to appreciate the importance of this symptom in its bearing upon the diagnosis. Indeed, this symptom alone, *cæteris paribus*, would seem to be unequivocal in differentiating abdominal hemorrhage from purely nervous shock.

The etiology of this case is apparently fourfold: (1) The fact that she was a hard-working woman; (2) that she was practically one of those "widows indulging in hymeneal pleasures, but who pretended to be chaste;" (3) the injury received from her husband nine years ago, followed by dysmenorrhœa; and (4) the abortion of last spring. The fourth eliminates the first and second, but whether the old injury or the recent abortion was the real predisposing cause seems impossible to determine.

In the history of this pregnancy it was observed that on June 27th, exactly six weeks after conception, she was prostrated by abdominal cramps, and obliged to remain in bed for three or four days. This attack was, in all probability, an early rupture, from which the patient recovered; the rupture having taken place, as Tait maintains in such cases, in that one-fourth of the tube which is in relation with the cavity of the broad ligament.

The successes of Lawson Tait, who has performed laparotomy at time of rupture in ten cases,[3] with nine recoveries, demonstrates the proper course to be pursued under the circumstances. To operate when the patient is *in articulo mortis* is the most serious question of all; yet the only case in this country recorded[4] as a success (that of Briddon) was operated upon under such circumstances; and Tait says, "Operate, if any chance of success."

Dr. R. B. Maury, however, advises[5] that "Our efforts at the time of rupture should be directed solely to rallying the patient and bringing about reaction."

All the successful operations at the time of rupture, including those of Veit, were preceded by due deliberation; but when there is no time for such deliberation the only justifiable course would seem to be to rally the patient, with the hope of holding in abeyance the almost inevitably fatal issue, until the circumstances will have sanctioned the propriety of an operation.

[2] West Twenty-third Street, New York.

A Change of Name.—The *Aerztliches Intelligenzblatt*, of Munich, after an existence of thirty-two years, has suddenly expanded into a large and handsome weekly journal, and with its growth has taken the name of the *Münchener Medicinische Wochenschrift*. It presents a very handsome appearance in its new dress, and with original articles by Maas, von Ziemssen, Riegel, and others, it ought to satisfy the most exacting of its readers. We congratulate our esteemed contemporary on its prosperity.

REMOVAL OF THE PLACENTA AFTER ABORTION.

By W. T. CHEATHAM, M.D.,

MEMBERS N. C.]

The management of abortions attended with retained secundines has been much and ably discussed of late by many of the most eminent and experienced members of the profession, the preponderance of expression being decidedly to favor the immediate removal of the uterine contents when the ovum has been expelled, the placenta and membranes remaining behind. I will therefore substantially iterate my impressions on this subject as published in the October number of the *North Carolina Medical Journal*, 1884, advocating the immediate removal of the placenta.

The danger attending abortions is to be estimated by many circumstances; first, the period of gestation arrived at, also the previous state of the patient's health; again, by the quantity and rapidity of the hemorrhage, and by the difficulty of checking it; and again by the length of time that the patient has been suffering hemorrhage; and again by the degree of expulsive action as manifested by pain. The principal, if not only, source of peril, is the loss of blood; to that, therefore, our attention should be chiefly directed.

The earlier the period of gestation, the more vigorous the patient's health, the less the amount of hemorrhage, and the less the difficulty of subduing it, the less will be her peril. The state of the uterine action must not be underestimated in forming our judgment; for the more rapidly and vigorously the uterus contracts on its contents, the more likely will it be to expel the ovum speedily, and entirely to empty its own cavity, to close its open vessels, and to put an end to an immediate flow of blood. It has been promulgated as a principle that abortions occurring in the early periods of gestation bring with them but little danger. This proposition is by no means correct; my experience is that it is not without many exceptions. Many women I have seen suffering from the most frightful symptoms of hemorrhage, under abortions of very early periods.

I well remember, in the first year of my professional life, meeting with an abortion occurring about the seventh week, of a most perilous character, and I do not remember ever since having seen a woman in so great a peril as she appeared to be recover. Not only was the bed on which she lay thoroughly saturated with blood, but a quantity of the vital fluid had poured through and lay in a pool upon the floor. She was perfectly senseless, blanched, and cold, and in a state of constant jactitation, with which occasional convulsive phenomena alternated. The respiration and circulation were so imperfect, at one time, we thought the vital spark had fled. This woman made a slow recovery, and for many months her health was quite precarious.

The first question to be considered when called to a case of threatened abortion, is, can the expulsion of the uterine contents be prevented? The answer to this usually depends on the dilatation of the os, and the amount of hemorrhage. If the hemorrhage has been active, and the amount of blood lost considerable, the probability is that the utero-placental connections are so separated that abortion must ensue. Should a vaginal examination show the os to be well dilated, and the membranes bulging, matters have gone so far that we cannot reasonably expect to prevent expulsion of the uterine contents; however, more frequently, on our arrival at the bedside, we find that the ovum has been expelled, and the secundines retained. The os being sufficiently dilated to admit the passage of the embryo, it is safe to conclude that it will admit the entrance of the fingers, and is in a condition to admit of manual or instrumental interference. It is admitted by all who have given this subject consideration that when the ovum is expelled, and the placenta remains behind, we may expect the danger from hemor-

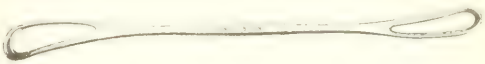
rhage to continue until the placenta and membranes are expelled.

Under these circumstances, and leaving out of consideration the danger of septic difficulties likely to arise from a retained and decomposing placental mass, it is incumbent, as a means of safety to the patient, that we empty the uterus of its contents as speedily as possible, and avoid immediate danger from hemorrhage.

It is not necessary for our purpose that we enter into a discussion of the management of abortions, as recommended in the various works on obstetrics, and usually practised, but may confine our remarks to the immediate removal of the uterine contents when abortion cannot be prevented. We are told to employ the fingers as a means of extraction, to place one hand above the pubes, press the uterus down and make steady the fundus, while with the other we pass the fingers into the uterine cavity and scrape out the offending mass, thus terminating the danger. In patients with thin, pliant abdominal walls, we will most likely succeed in removing the secundines by this method, but this finger-delivery not infrequently is exceedingly difficult of accomplishment. It is not an infrequent occurrence to meet with cases in which the examining finger can with difficulty be brought in contact with the more or less detached placental mass within the uterine cavity, this member being too short to explore the cavity to its fundus, scrape off, and extract the placenta. In stout women, of a nervous, sensitive, unmanageable disposition, with a deep vagina, and thick abdominal walls in connection with a firmly-contracted uterus, rendering the cavity too narrow to permit flexion of the fingers and manipulation of the retained products after they have been forced through the internal os, we shall be thwarted in our efforts and must of necessity look to other and more efficient means to accomplish the desired end. When the placenta and membranes cannot be removed with the fingers, various instruments have been devised for seizing them and bringing them out. Hodges' modification of the bullet-forceps is a failure, for the reason that you cannot maintain your hold on the placenta after you have seized it with the instrument. The same objection does not obtain to Dewees' hook, but this is a sharp instrument, and incalculable damage may be inflicted even when used with skill and caution.

The Duck-bill, Mundé's, Loomis', and other placental forceps of like construction are safe and excellent instruments, but are not easy of application, it being necessary in many cases to use the speculum in order to apply them with the proper precision necessary to a successful extraction of the placenta.

I conceive that most practitioners of an intelligent experience, who are not too faint-hearted to act in an emergency, or are not converts to the so called conservative doctrine and practice of tamponing, washing, and waiting on nature to accomplish the repulsion and delivery of the secundines unaided, have felt the necessity for an instrument that would obviate the delay, and avoid difficulties often incident to the use of the speculum. The immediate surroundings, and, it may be, the feeble and exhausted condition of the woman, would make it not impracticable, but difficult, and perhaps hazardous, to carry this plan into execution. The foregoing, I apprehend, will not apply so aptly and with the same force and emphasis to our city brethren, who enjoy so many facilities and advantages not practically within the domain of the country practitioners, to whom they apply with peculiar aptitude. The city doctor can give his patient his continuous personal attention, if required. Should his numerous engagements intervene, he has professional friends at hand who will promptly supply his place. Therefore, he can more consistently wait, and trust to the conservative management, than the busy country practitioner, whose patients are scattered over a wide scope of territory, many miles apart, and far from his place of residence, and the demand for his services being too great, and his time too precious, to permit a prolonged visit. To tampon, direct the usual remedies for hemorrhage, and leave the subsequent management, during his unavoidable absence, to timid friends, or, worse still, to the ever-present and officious country midwife, would be to jeopardize the immediate safety and future health of the woman, to the detriment of his good reputation. Having for many years exercised the functions of the country doctor, I have often been put severely to the test by difficulties arising during attendance on abortions. On one occasion, in a critical case occurring at the third month, with some constitutional symptoms, the embryo having been expelled fourteen days, I was reduced to the extremity of extracting the retained putrid and decomposing secundines with the handle of a common pewter spoon, it being the only available instrument. Many are the devices of our country brethren when pressed by an emergency. One tells me he has used a loop of common wire as an extractor; another frequently resorts to the sharp curette as an aid to the fingers, with fair success, especially in cases occurring at an early period of pregnancy. In the February, 1883, number of *The American Journal of Obstetrics*, Dr. Mundé has published a description of a placental curette, a most excellent instrument for detaching and scraping out a firmly-adherent or morbidly-attached placenta. It is peculiarly adapted to difficult cases occurring about the second month. Having for many years been convinced of the unsatisfactory teachings and practice usually adopted, as too compromising, in February, 1880, I devised an instrument which has proved satisfactory in my hands, having used it with uniform success, never failing to turn out the uterine contents with ease, safety, and expedition. It is ten inches long, with both ends fenestrated and scoop-shaped, representing two instruments combined in one (a large and small size), either being used, when required, for extracting the uterine



contents. Its edges are oval and smooth, preventing the possibility of danger by cutting, and it is delicately constructed, yet sufficiently strong for practical purposes. When it is apparent that abortion cannot be prevented, and the hemorrhage is severe, with the os sufficiently dilated to admit the index-finger, the placental scoop can be introduced and the uterine contents quickly turned out, putting the patient beyond danger from hemorrhage and septic difficulties likely to supervene when we have a retained and decomposing mass of secundines.

In order to use the scoop intelligently and successfully, the patient should be placed upon her back, with her extremities drawn up and supported by an assistant, or, if preferred, put upon her side, with her hips brought close to the edge of the bed, the extremities flexed and held apart by assistants. With the index-finger in the os as a guide, the scoop should be introduced with its convexity pointing to the posterior intra-uterine surface and passed well up to the fundus. With the left hand above the pubes to steady the uterus, the instrument with the other should be made to sweep the uterine cavity, making its entire circuit two or three times, the edge impinging on the uterine parietes, breaking asunder all placental connections, and then withdrawn with its scooped surface presenting posteriorly, the point of the instrument pressing the uterine surface, bringing with it the product.

Occasionally, after having detached the placental mass, on the withdrawal of the scoop it will be found loose in the os, nothing remaining but to take it away with the fingers, or, if necessary, introduce the instrument again and fish it out. The small-size scoop is of practical utility in abortions occurring from the sixth week to the end of the third month, while the large size meets the demand in those cases occurring from the third to the fifth month, inclusive.

Having in my mind several cases in which the scoop

proved a success after my fingers had failed me, I will give two or three from memory, as succinctly as possible.

CASE I.—A lady, while in town shopping, felt a sudden rush of blood from her genitals, which for the moment excited alarm. The cessation being almost as sudden as the attack, and experiencing no inconvenience, she rode home five miles in a buggy without exciting a return of the hemorrhage. For two months she had an occasional hemorrhagic discharge, the quantity not being sufficient to excite apprehension or cause inconvenience. She was again suddenly seized with an active flow, accompanied by severe bearing-down pains. When I saw her, two fingers could with difficulty be forced through the cervix into the uterine cavity, meeting with an oblong oval body, which gave to the touch a semi-solid elastic feel. Not being able to accomplish its removal with the fingers, the small-size scoop was employed, a separation and extraction effected, the product proving to be an encysted placenta, the embryo having been expelled two months previously.

CASE II.—Embryo expelled at the seventh week, placenta retained with active hemorrhage. Being unable to pass the fingers sufficiently far to detach and extract the offending product, the small-size scoop was employed with easy success.

CASE III.—Fifth month, with fœtus expelled three days previously. Physician in attendance had succeeded in getting away about one-half of the placenta. The os was sufficiently dilated to admit two fingers, but the firmly-contracted condition of the uterus prevented a separation and extraction of the retained portion. The scoop was employed, the attachments broken up, and the remainder of an offensive and decomposing placenta removed.

CASE IV.—Gestation nearing fifth month. Embryo expelled thirty-six hours previously. No hemorrhage since expulsion of embryo. Could pass the fingers into the uterus, but owing to its firm contraction, and narrow condition of its cavity, they were unavailable as a means of delivery. The large-size scoop was employed, the adhesions broken up, and the placenta brought out.

All of the above cases made safe and rapid recoveries. I could make reference to others, but will refrain, as I have already extended my remarks beyond the limit first intended.

A NEW FORM OF CONTINUOUS FLOW SYRINGE.—Dr. Wm. R. Leonard, of New York, has devised a syringe with a single bulb, similar in appearance to the ordinary Davidson apparatus, by which he claims a continuous flow of the injected fluid may be obtained. The modification consists in a longitudinally corrugated outlet-tube which becomes dilated by the pressure of the fluid forced from the bulb, and then by its elastic force insures the steady flow of the fluid during the relaxation of the bulb. The weight attached to the extremity of the receiving-tube is covered with rubber, so as to prevent the clinking in the vessel which is so disagreeable to some nervous individuals. The nozzles are made of hard rubber and are secured by simply pushing them into a soft rubber socket, no screw attachment being provided.

UNALTERABLE COCAINE SOLUTIONS.—Solutions of cocaine, as those of morphine, atropine, and some other alkaloids, when made with simple distilled water, rapidly become spoiled through the growth of a fungus. Such impure solutions may cause injury to the tissues when injected, or may excite inflammation of the conjunctiva when employed in ophthalmic practice. In order to obviate this Dr. George Abbott recommends a solution in camphor water. He has kept solutions of atropine to which camphor (one grain to the ounce) was added for over a year, and has not seen any micro-organisms develop. Camphor is especially suited for preserving solutions intended for use in the eye.

Clinical Department.

TRACHEOTOMY IN A CHILD THIRTEEN MONTHS OLD, FOR THE REMOVAL OF A FOREIGN BODY.

DR. E. B. WARD, of Greensboro, Ala., writes: "On November 22d, early in the morning, a child thirteen months old was brought to my office, suffering from considerable difficulty of respiration. The parents had walked ten miles the night before, bringing the child in their arms. The evening before the child was playing with some peanuts and accidentally got one into the windpipe. She was discovered to be strangled and was jerked up and struck on the back, and various other means were resorted to to relieve the little sufferer, without avail. When I saw the child I found it evidently suffering from some obstruction in the air-passages, and on an examination into the history of the case a diagnosis of a foreign body in the trachea was made. This was confirmed by my father, Dr. T. R. Ward, who saw the case with me. The respirations were labored, harsh and rattling, the child's face was somewhat swollen and cyanosed, and on examination coarse crepitant râles were heard over the whole chest. It was plain that the only relief was from an operation, but the parents at first objected to this, so we decided to wait and requested a consultation. It was three o'clock in the afternoon when the consultation was held, Drs. Peterson, Young, and Inge being present. At this time the child's symptoms were growing rapidly worse, respiration was very difficult, and suffocation seemed imminent. Tracheotomy was plainly indicated as a *dernier ressort*. The patient was anæsthetized and a free opening was made in the trachea. The child's neck was short and deeply covered with adipose. Notwithstanding the engorgement of the lungs and the partial cyanosed condition, chloroform was well borne and did not seem to aggravate the symptoms in the least, but enabled me to perform the operation and make the necessary dissection with ease and precision. The thyroid veins were plainly visible and were held out of the way while the fascia was divided between them, thus exposing the trachea to view. The incision was about one inch in length in the integument, and about one-third of an inch in the trachea. There was not much loss of blood. Just after the incision in the trachea was made a gush of air came through, and we expected to see the foreign body ejected through the opening. While attempting to insert a tracheotomy tube the foreign body was dislodged, but instead of escaping passed by and down lower in the trachea below the wound and became fixed, when respiration instantly ceased, and to all appearances the child was dead. But artificial respiration was diligently resorted to, and I can fully attest the value of this means in this case. A female catheter was introduced in the trachea, and air was blown into the lungs while pressure on the walls of the chest was made to simulate expiration. After awhile our efforts were crowned with success, and after a period of about five minutes had elapsed since the child last breathed, it gave a gasp and the lungs slowly began to work again. The foreign body now was again dislodged by an effort of the child to cough, and in passing the opening of the trachea a half of a parched peanut with the skin attached was seized with forceps and extracted. The respiration, which was hurried previously, gradually became slower and fuller, the child rallied, took nourishment, and rested well through the night. The tube was left *in situ*, as was thought best, and instruction carefully given the nurse to clear it when it filled up. But through neglect, after all the precautions, it was allowed to fill up with mucus, and the child died from suffocation before I could reach it. Thus was wrecked upon an unseen rock a life which science had successfully guided over the breakers, and the art of surgery was robbed of its just prize."

CATIVÍ.

UNDER this title, Dr. Luis Lazo Amàga, of Guatemala describes an affection of the skin, occurring in Honduras, which is characterized by spots of different colors disseminated over the entire body but occurring in closer aggregations in certain localities. He writes: "There are two kinds of *cativí*: one which is accompanied by pruritus and abundant desquamation, and another which wants these qualities, although sometimes we observe a slight pruritus without desquamation.

"The sick present no other symptoms than those enumerated. They exercise their functions just as in a state of health, and the skin, apart from its discoloration, and its scurfy desquamation presents no signs of inflammation.

"The color of the spots varies much, depending in a great part upon the color of the skin, since the whites have many red, black, and blue spots, while the negroes have white and blue ones commonly. At times but a single color is observed, but usually there are several, and from the appearance thus caused those suffering from this affection are called by the natives *pintados* (painted) or *manchados* (spotted).

"The *cativí* is a very contagious disease, as I had occation to observe in an individual who apparently acquired it from having bathed in a river in company with a *manchados*. On an estate of mine, situated in the Department of Olancho, in the Republic of Honduras, the laborers who are not *manchados* avoid making use of the agricultural implements which the *manchados* have handled, because they assured me that the disease was transmitted in this manner.

"What I was able to notice in my sojourn in that place was that the *scaly cativí* is more easily transmitted than the *smooth* kind, and that the first appears in children almost from birth (indeed it is said to be sometimes congenital), while the second does not develop itself before seven years.

"The disease may be hereditary, particularly the *scaly* kind, although some children of the *manchados* do not have it; and I have seen families in which the father and some of the children were suffering from it, while the mother and the others were no

"I am led to believe, from repeated microscopical examinations, that the scaly form of *cativí* is of parasitic origin, but the smooth variety shows nothing to indicate the presence of a fungus or of any low form of animal life such as is found, for example, in scabies. The cause of the disease is unknown; some attribute its origin to the action of the water or to the bites of insects, but my own observations lead me to reject these theories of the etiology of the *cativí*. It is a somewhat curious fact that, in spite of the repugnant aspect of the disease, its subjects do not appear to suffer mentally from their affliction, nor do they shun intercourse with healthy persons.

"No curative method, based upon observation, can be established, because the *manchados* never seek the advice of a physician. The only case of medical cure which I have seen was that of the man, before mentioned, who acquired his disease while bathing, and to whom remedies were given as soon as the first spot appeared. Only five spots were developed, and thanks to an external mercurial treatment, continued for some time, they disappeared, leaving only a slight discoloration of the skin at the points where they were situated.

"I believe that the disease is always curable, and this view is also held by the leading physician in Honduras, Dr. Gamero, whom I once asked if the cativí could be cured. 'When the sick wish they can heal themselves,' he answered, 'but generally they do not wish it; if men, because it exempts them from the military service; if women, because they do not need to.'"

THE BEST SPECIALTY IN MEDICINE is common sense, founded on experience in general practice.

Progress of Medical Science.

COFFEE AS A CAUSE OF PRURITUS.—M. Brown-Séquard states (*Gazette des Hôpitaux*, November 3, 1885) that he has several times seen a most intense pruritus excited by the use of coffee. He relates the case of a lady who suffered from pruritus vulvæ every time that she drank a cup of coffee, the trouble disappearing when she discontinued the beverage. A man, sixty years old, who for forty years had lived in a laboratory filled with the odors from dead bodies of animals, living on bread and black coffee in order to save money to buy animals for experimental purposes, was seized with a most intense pruritus of the anus. The trouble was relieved only after he had given up coffee, and returned each time that he resumed its use.

PECULIAR DEFORMITY OF THE FINGER.—At a meeting of the Academy of Medicine of Paris (*Gazette des Hôpitaux*, November 5, 1885) M. Jules Guérin presented a woman and her three children, each of whom had an angular and lateral deformity of the first phalanx of the index fingers of both hands. The reporter said that the origin of this deformity was to him inexplicable; there was no muscular lesion, no rachitis, and no history of traumatism, and the only possible cause was to be referred to maternal impressions. The mother stated that she had had her deformity on her mind during the entire period of each pregnancy, fearing that her offspring should be similarly affected, and in each instance her fears were realized. M. Guérin proposed to divide the lateral ligaments in order to effect a reposition of the deflected phalanx.

HEPATIC ABSCESS IN TYPHOID FEVER.—Abscess of the liver is not uncommon in dysenteric ulceration of the intestines, but is extremely rare after ulcers occurring in typhoid fever. Dr. Bokai relates the case of a child, ten years old, who was admitted to hospital after having been ill for several weeks with typhoid fever. The only physical signs discoverable were bronchial râles and the evidences of pulmonary engorgement. There was no enlargement of the liver. The course of the fever was not modified by quinine, and after a short time there was a sudden aggravation of the disease, vomiting of greenish matters occurred, and the child died. At the autopsy a large abscess was found in the right lobe of the liver, the left lobe was filled with a number of small abscesses, and a rupture had occurred in the peritoneal cavity, which contained nearly thirty ounces of pus. Peyer's patches were enlarged and presented the characteristic ulcerations of typhoid fever.—*Rivista Clinica e Terapeutica*, December, 1885.

TREATMENT OF DISEASES OF THE STOMACH.—Dr. Talma employs with good effect hydrochloric acid in gastric affections, giving it in a warm draught containing 1 part of acid to 750 of water. The best results are obtained when this solution is sipped slowly after each meal. It prevents the decomposition of the contents of the stomach and by its antiseptic action exerts a favorable influence upon the diseased walls of the organ. It is necessary, of course, to regulate the diet most carefully, avoiding all fatty substances in ulcer or cancer of the stomach.—*Rivista Clinica e Terapeutica*, December, 1885.

INTRA-UTERINE ERYSIPELAS.—Dr. C. H. Stratz relates a case of this nature. A young woman, pregnant for the first time, suffered from several attacks of erysipelas, during the last of which labor began. The child, which was alive and of normal weight, presented the epidermis of the whole body, especially about the buttocks, so loose that it could be pulled off in strips. The mother had facial erysipelas, originating in a crack at the corner of the mouth, and the genitals and other parts of the body were entirely free from the disease.

Voluntary Acceleration of the Heart's Action.—Many cases are reported in medical literature of individuals who possess the power to increase the rapidity of the cardiac pulsations by a simple effort of the will. Dr. Tarchanoff had an opportunity of studying this phenomenon in a student who was able, without any apparent effort, to raise the pulse-beats from 70 to 105 per minute. He concluded that this was accomplished through excitation of the accelerator nerves, rather than by depression of the inhibitory centre. In observations upon a number of similar cases he found that the power of voluntary acceleration of the heart was possessed by individuals who had a special muscular expertness. They were able to move the external ear muscles and the platysma-myoid, or could flex the terminal phalanges of the fingers, the other articulations being held extended. He says that this faculty of voluntary control over the heart is less rare than is generally supposed.—*Gazzetta degli Ospitali*, November 8, 1885.

Antipyrine in Epistaxis.—Dr. Lavrand reports some cases which serve to demonstrate the powerful hæmostatic action of antipyrine. It is certain and prompt in its effects, he says, and is much superior to perchloride of iron, as it is colorless and does not coagulate the tissues like the latter substance. It is used in aqueous solution, of the strength of 1 to 30, applied on lint and inserted as far as possible into the nares. The nostril is then compressed with the fingers so that the tampon soaked in the hæmostatic is in contact with a large extent of the mucous surface. By means of several applications thus made, M. Lavrand succeeded in arresting epistaxis which had persisted in spite of plugging of the anterior and posterior nares.—*Journal de Médecine et de Chirurgie Pratiques*, November, 1885.

Measurement of the Fœtal Feet during Parturition.—Dr. Gonner states that there exists an almost constant proportion between the size of the feet and of the head in the fœtus, and that it is, therefore, possible in breech presentations to estimate the difficulties which will be presented by the passage of the head. From a large number of observations he concludes that in general a foot measuring three inches in length will correspond to eight and one-half pounds in weight of the child, and if a foot is found of greater size the child will be found to exceed the average weight at term.—*Journal de Médecine et de Chirurgie Pratiques*, November, 1885.

Hæmorrhagia Neuralgica.—Under this name, Dr. Englisch, of Vienna, has described a peculiar affection of the lower extremities, accompanied by neuralgia, hemorrhage, and permanent wasting of the limb, five cases of which have come under his notice (*London Medical Record*). These patients, previously in good health and in comparatively comfortable circumstances, were suddenly, and without any precursory symptoms, seized with severe neuralgic pain in the course of the sciatic nerve. After continuing several days, it was succeeded by rigors and high fever, followed by sweats and evidence of considerable depression, and passing into a continued fever lasting several weeks, and exhibiting maxima of 100° F. to 105° F. On the third or fourth day from the commencement of the sciatic pain the limbs began to swell, a soft elastic mass extending from the ham to the hip, and gradually increasing in width, especially above, but not obliterating the form of the muscles, which stood out as if distended. A bloody infiltration next spread over the whole surface of the limb, and the veins appeared as pale brown stripes, such as are sometimes seen in septicæmia. The entire skin changed its color to that caused by deep sugillation. The connective tissue now became deeply infiltrated, and the bellies of the muscles could no longer be defined, the whole limb having been converted into a tense mass, sensitive to touch and quite stiff. The swelling was always greater on the posterior aspect of the limb, which might be flexed in consequence. The hollows of the ham, and on each side of the tendo Achillis, were obliterated. The feet were œdematous, rarely extravasated, and there might be effusion into the knee-joints, though not into the ankle. Both extremities might be affected, but one always more so than the other. From the appearance of the skin, tense, shining, and often red, these cases are usually admitted into the surgical wards under the description of cellulitis or phlegmon. They seldom proceed, however, to suppuration or breach of surface, the pain being due rather to the tension and the previous neuralgia. With the subsidence of the fever, the processes of repair or retrogression commence. These consist mainly in a shrinking of all the soft parts, most conspicuous in the muscles; their rounded form is lost, and the calf acquires an ape-like appearance. The skin shrinks at the same time, so that the tension remains almost unaltered. In extreme cases nothing is left but a mass of rigid connective tissue, in which the bones appear as if imbedded. These changes are most marked in the neighborhood of the ankle, which is completely ankylosed. In one of the cases which Dr. Englisch had an opportunity of examining, the skin was thin, tough, parchment-like, and so firmly adherent to the subjacent connective tissue as to be dissected off with great difficulty. The fasciæ appeared no longer as separate structures, but were inseparably blended with the surrounding tissue. The veins were thickened, and imbedded in the subcutaneous connective tissue. The muscles of the calf appeared as strands of connective tissue, but the tendons could for the most part be liberated from their sheaths. The proper substance of the muscles had disappeared, the sarcolemma alone remaining, with only a few disks here and there, and numerous oil-globules bore witness to the degeneration. The blood-vessels, thickened, and their lumen reduced or even impervious, were immovably imbedded in a mass of fibrous tissue. The capsules of the knee-joint and of the ankle contained no excess of fluid, but were thickened so as to impair the mobility of the joints. The nerves were not visibly altered, but were imbedded, like the vessels, in a mass of connective tissue. The ends of the bones were normal, and the muscles had undergone little alteration, although paralyzed. Beyond evidence of tubercular disease, the other organs were normal. In a second case, which came under observation two years after the commencement of the disease, the ankle was rigidly fixed at a right angle, passive movement being possible only to a very slight extent, and causing intense pain. Movement in the knee was less affected. The rotundity of the calf was quite lost, and the patient walked with great difficulty, and as if on a wooden leg. The pathology of this disease is very obscure. One might be inclined to look on these cases as severe forms of scorbutus; but in none of them were the previous circumstances of the patients such as were likely to induce scurvy, and in one only did the prodromal symptoms suggest such an origin. The intense sciatic pain was a prominent feature. Rigors, fever, etc., are met with only in severe and acute cases of scurvy; but in such extravasation of blood, sponginess of the gums, and lesions of the lungs and intestinal canal, are never absent; whereas, in these patients there were no petechiæ, and the gums, lungs, and bowels were healthy. So were the kidneys in four cases; in one only was there transient hæmoglobinuria. In their character, too, the extravasations differ from those of scurvy; they never appear in the cutis itself, but in the subjacent connective tissue and the muscle-substance of the lower extremities only. The effusion, again, is not of normal blood, but rather such as is seen in septicæmia, and after injections of septic and foul matters into the veins. It follows closely the course of the vessels as brown streaks on the surface of the limb. The changes in the appearance of the skin resemble those which accompany deep extravasation; but the effusion is here, as well as in the infiltration of the tissues, a bloody serum, which accounts for

the absence of any more or less clearly defined petechiæ. The changes in the blood itself are a slight diminution in the number of the white cells, and a marked reduction in that of the red discoid corpuscles, which are replaced by spherical and diverse-shaped red cells, in part nucleated, with an astonishing number of the so-called microcytes, or cells resulting from the division of the former. These changes correspond to those which are observed in osteomyelitis, and would indicate the origin of the disease in a grave alteration of the character and composition of the blood. The consequences and remoter effects, especially the atrophy of the muscular tissue, deserve special study. So soon as the absorption of the infiltration sets in, the muscle-substance begins to waste, and the collective structures of the limb are gradually but uninterruptedly transformed into a connective tissue like that of cicatrices. In several cases this transformation is complete; but even in those in which it is not so, and some muscular power is retained, the wasting of the limb persists many years. The disease seems not to be without its influence on the general health In one of Dr. Englisch's cases there were already symptoms of pulmonary tuberculosis, but this afterward advanced so rapidly that the patient died within two years. A second, though her lungs were quite sound at the time, and there was no history of hereditary tendency, speedily succumbed to tubercle of the lungs and genital organs. A third, left helpless by the atrophy of the limbs, sank not long afterward in like manner. Such being the rapid course of the disease, the treatment must be energetic. The persistent application of cold seems indicated, with a view to check further hemorrhage so long as pain continues. When this has abated, the absorption of the exudation must be promoted by stimulating poultices; later by warm fomentations, resolvents in the form of ointments, massage, etc. The early employment of electricity is to be specially recommended, to maintain the functional activity of such muscle-tissue as remains, and endeavors should be made to reduce the callosity and to restore movement to the joints by means of warm baths, etc. The further treatment must be conducted on general principles.

Hæmoptysis in Syphilis.—Dr. Reyes records some cases of hæmoptysis during the second stage of syphilis, in patients treated by the green iodide of mercury. In one case the hæmoptysis disappeared when the iodide was stopped, and recurred each time this drug was recommenced. Dr. Reyes suggests that in some persons this drug produces a fatty degeneration of the capillaries of the respiratory passages, thus giving rise to rupture and hemorrhage.

The Diaphoretic Treatment of Nephritis.—Following the suggestion of Professor Manassein, Dr. Hess ("St. Petersburg Inaugural Dissertation," 1885) made comparative observations on the effects of the treatment of nephritis by wet packings, hot baths with subsequent wrappings in woollen blankets, and hot-air baths. The experiments were carried out at a hospital in St. Petersburg on six patients, two of whom suffered from chronic interstitial nephritis, two from chronic parenchymatous nephritis, one from acute parenchymatous nephritis, and the last presented an exacerbation of chronic parenchymatous inflammation of the kidneys. The number of observations was sixty (fifteen wet-packs, twenty-four hot-water baths, and twenty-four hot-air baths), each of the patients being alternately subjected to each of the diaphoretic procedures. The author arrived at the following results: 1. The least rise in temperature of the body is produced by wet-packings, the temperature of water used being 45° to 50° F., the duration of packing an hour; the greatest by hot-water baths, at 72° to 80° F., of twenty to thirty minutes' duration; hot-air baths, at 90° to 130° F., of twenty to thirty minutes' duration, stand midway between the two methods. 2. While the temperature falls already in twenty minutes after the packing, it remains elevated even an hour after a hot-air or hot-water bath. 3. After hot-water baths the temperature returns to its normal level more slowly than after hot-air baths. 4. Under the influence of wet-packing the pulse becomes slower, the retardation remaining considerable even twenty minutes after the pack; on the contrary, it is considerably quickened from hot-water and hot-air baths. The increase in its frequency, on the average, is greater in the case of air-baths than in that of water-baths; but in the former the pulse returns to the standard more rapidly than in the latter. In both cases it remains still quickened even an hour after the bath. 5. Under the influence of wet-packing, respiration is quickened, but very moderately. It becomes far more frequent after hot-water and air-baths, especially after the former. It returns to the normal most rapidly after hot-water baths. 6. The least powerful sudorific effects are produced by wet-packings; the most powerful by hot-water baths, with subsequent wrapping in woollen blankets. Hot-air baths occupy a middle stand between the two. 7. In spite of the fact that hot-water and hot-air baths are accompanied by fairly strong symptoms of excitement, while wet-packings, on the contrary, produce a soothing effect on the nervous system, the patients most readily subject themselves to hot-water baths, but not to wet-packings; a circumstance which must be ascribed to a stronger diaphoretic action of the said baths, and to an improved subjective feeling of the patients after hot-water bath.

Periproctitis Simulating Typhoid Fever. Professor Lücke (*Deutsche Medicinal-Zeitung*) relates the case of a strong and healthy man who was struck on the abdomen with a pole, but without receiving any apparent injury. Two weeks later he was seized with typhoid symptoms, high fever, and diarrhœa. These were followed by tenesmus, bloody and then purulent discharges, a gangrenous piece of the rectum was passed, and soon the man died. At the autopsy there was found a perforation in the posterior wall of the rectum, and a large fecal abscess extending to the sacrum. There were no typhoid lesions in the intestinal canal, no caries of the sacrum or coccyx, and no apparent actinomycosis. The author believed that the affection was caused by the lodgement of the actinomycosis fungus in the folds of the rectum, giving rise to ulceration and abscess. The original fungus of actinomycosis can often not be found in abscesses of which it is the cause.

Perforating Ulcer of the Bladder.—Dr. Oliver describes (*Medical Times and Gazette*) an affection which has hitherto been looked upon as more or less peculiar to the stomach and duodenum, viz., perforating ulcer of the bladder. This affection is always acute, and is especially apt to recur. It usually develops without signs of inflammation or suppuration, and, as in the stomach and other parts of the intestinal tract, apparently results from the plugging of vessels which run in and nourish the coats of the viscus. Embolism and thrombosis are the most frequent causes of perforating ulcer in the bladder. The author adds that, in his experience, a rheumatic diathesis augments the tendency to this affection. Females are more prone than males, and especially about the period of puberty. The symptoms and course of this disease are usually very insidious, and fatal peritonitis may result before the condition has been recognized. Pain referred to the hypogastrium, and aggravated by pressure, or by over-distention of the bladder, is a frequent symptom. There is frequency in micturition, with sharp, cutting pain at the end of the process. The most distressing symptom is tenesmus, which results from spasm of the muscular coat, and may continue for some time after the organ has emptied itself. The treatment is rest and milk diet; opiates must be given to relieve pain.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 2, 1886.

THE THERAPEUTICAL USES OF OXYGEN.

OXYGEN composes one-fifth of the earth's atmosphere, one-half of the earth's crust, and eight-ninths of the water of the globe. It is an essential part of the daily food, the adult organism using about two pounds daily; over two-thirds of a quart is constantly circulating in the blood, and it is the most potent factor in the processes of tissue growth and change. It is not very strange, therefore, that oxygen should be thought to have great therapeutic possiblities, and that the imagination of the enthusiastic should at times be a little carried away by apparent evidences of its potency.

Oxygen exists in three forms: the nascent, represented by O, the ordinary form, O_2, and the condensed form, ozone, O_3. It is O_2 with which the organism has ordinarily to do. Oxygen enters the system mainly by the lungs, it is absorbed by the serum, and then is quickly taken up by the hæmoglobin of the blood-corpuscles to the point of almost complete saturation, *i.e.*, within nine-tenths of the point of saturation. The oxygen here is not in the form of ozone, as has been sometimes asserted, but is in its neutral form (O_2), and in loose combination with the hæmoglobin (Hoppe-Seyler and Pflüger). The oxygen exists to the extent of about 17 volumes per cent. in arterial blood. This normal proportion cannot readily be changed by any safe artificial methods. The inhalation of compressed air, or pure oxygen, and the practice of rapid respiration, may perhaps increase the volume per cent. a trifle. Regnault and Reiset have shown that warm-blooded animals in an atmosphere of pure oxygen do not absorb more oxygen or excrete more carbonic acid gas than in ordinary air, and P. Bert admits that even in an atmosphere of compressed air there is only a slight increase in the per cent. of oxygen in the blood.

So far as we can learn, therefore, all careful experiments show that in healthy warm-blooded animals the inhalation of pure oxygen causes almost no increase in the amount of oxygen in the blood. This amount is dependent upon another factor, *i.e.*, the amount of hæmoglobin in the blood. If this is increased, the oxygen amount is increased also, and in the same ratio the per cent. of iron—a fact of some significance.

It is the opinion of Rossbach and Nothnagel that oxygen inhaled in any manner whatever has no other effect in kind than the ordinary air supplied in extra abundance.

"Good, pure air, free from injurious gaseous, or solid impurities, has the same therapeutic effects as the inhalations of pure oxygen."

Oxygen has been recommended for a large number of diseases, *e.g.*, chronic phthisis, scrofula, epilepsy, diabetes, neuralgias, anæmia, asthma, pneumonia, asphyxiation, poisoning with toxic gases, intermittent fever, etc. The best results appear to have been obtained in the dyspnœa of pneumonia, asthma, in asphyxiation, gas-poisoning, and anæmia. Its value in chronic disorders of nutrition is still *sub judice*, and a practical objection to its use is the difficulty and expense of administering it in large amounts for a considerable period.

We cannot quite agree with the somewhat dogmatic views of Rossbach and Nothnagel, that the therapeutic use of oxygen is without a physiological basis. It is possible that the systematic, very slight increase in the per cent. of oxygen in the blood, caused by inhaling the pure gas, may give an impetus to the growth of hæmoglobin, especially when that substance is below the normal in amount. In other words, oxygen may stimulate hæmatosis just as iron is believed to do.

A NAVAL MEDICAL AND SURGICAL HISTORY OF THE REBELLION.

THE Secretary of the Newport Medical Society writes us:

"At the regular monthly meeting of the Newport Medical Society, held December 2d, it was voted that the associate member, Dr. Ayre, of the United States Navy, be requested to personally act with the Newport Medical Society in securing the publication of the valuable medical history of the United States Navy during the War of the Rebellion. A large portion of this material is ready for publication; but, owing to the want of Congressional appropriation, is not available for the use of the medical profession.

"The liberal aid afforded the Army Medical Department in publishing the 'Medical and Surgical History of the War of the Rebellion' is sufficient excuse, if any be needed, for pressing the importance of an appropriation for the naval medical and surgical history."

No single literary labor has done more to elevate American medicine in the eyes of the world than the editing of the volumes of medical and surgical history of the war by the Medical Bureau of the War Department. We sincerely trust that the surgeons of the navy may be given the means of carrying out a similar work. We have no doubt that the unanimous sentiment of the profession in behalf of the project can readily be obtained. We wish we could believe that this would carry weight with Congress.

THE CHANCES OF SUCCESS IN THE PRACTICE OF MEDICINE.

IT would be a matter of much interest if some comparative studies could be made showing the relative proportion of successes and failures in the learned professions and in business. At present the medical student is sent off from his Alma Mater with positive assurances that, if he will labor faithfully and wait patiently, success is certain to come. Is this the fact? It does not appear to be so with English medical students, at least. Sir James

Paget has traced the course in life of one thousand medical students, taken at random from an English college. About five per cent. of them failed utterly, while nearly ten per cent. more left the profession without giving it a fair trial; one-half made a fair living, six and a half per cent. achieved considerable success, and two and three-tenths became eminent. Of the whole number who began, less than two-thirds achieved any kind of success.

Such facts as these rather tell against the prevalent view that a man who chooses the medical profession is quite sure of in time getting a living. Yet we often hear this advice given to young men by those who have had some experience in the uncertainties of business.

Whether Sir James Paget's figures will apply to the United States, it is impossible to say definitely. The opportunities for a successful career are naturally much greater here, and if it were not for the fact that competition is twice as active a much larger percentage of successes would be scored. As it is, the probabilities are that of the four or five thousand medical students who are annually graduated by our schools over one-third of them fail or fall by the way.

THE EFFECTS OF CHEWING-GUM.

The following appears in the columns of *The Sun*: "Two medical journals are fighting over chewing-gum. One thinks it preserves the teeth, develops the gums, and should be encouraged; the other points out the injurious draught upon the salivary glands and digestive organs, and its crushing effect upon female loveliness." We have searched in vain for the records of the interesting controversy referred to, and must conclude that it originated *de novo* in *The Sun* editorial office. It is possible that two medical journals might quarrel over the subject of chewing-gum, but physicians in general will quite agree, we think, that the practice should be indulged in only with the greatest moderation. The practice of stimulating one's secretions for the sole purpose of experiencing the pleasurable sensations connected with their flow is not a safe one. There may be an inebriety in chewing rubber-gum, and real sensuality in persistent indulgence in aimless mastication.

THE CARNEGIE LABORATORY.

It is a source of great gratification to find that well-equipped laboratories for purposes of carrying on original research in medical science have been established in this country, despite the absence of Government aid. In this city there has been a particularly urgent need of some such institutions, and the erection and endowment of the Carnegie Laboratory marks a distinct step forward in the medical history of our metropolis. The influence of well-endowed laboratories for exact scientific research is not limited to those who have the opportunity of directly utilizing them, but extends to the whole community. We have no doubt that the work done in Carnegie Laboratory will raise the standard of work done in the medical societies of our city.

The Bellevue Medical College is to be congratulated on having obtained so good an ally as Mr. Carnegie.

SUBSTITUTION OF DRUGS IN PHYSICIANS' PRESCRIPTIONS BY [illegible]

A correspondent from Chicago writes us a very indignant letter over the discovery which he has made, that a druggist has been substituting other preparations for that which he prescribed. We can imagine that, with the immense number of proprietary preparations in the market, the temptation for the druggist to use some other manufacturer's pills, hypophosphites, oil, etc., than the one prescribed, must sometimes be very great. The only honest course, however, is for the druggist, if he has to use another firm's preparation, always to inform the physician of the fact.

Furthermore, the physician on his side, should be very careful in prescribing certain manufacturers' preparations. It is hardly fair to compel a druggist to keep half a dozen lines of quinine pills, fluid extracts, or hypophosphite compounds, when most of them are probably of about equal merit.

News of the Week.

Annual Report of the Surgeon-General of the United States Army for the Year ending December 31, 1884.—The report shows that in an army of 24,035 men, there were 263 deaths (10.9 per 1,000), and 36,829 cases of sickness. The average number of days lost by sickness to each man was 16.2, and the average number of days each case was treated was 10.6. This report compares favorably with those of preceding years, showing a decided decline in sickness. The rate is lower also than that of the British and French armies, though higher than that of the German army, the latter having been on a peace footing. Among the interesting additions to the Museum during the year may be mentioned, a model of the course of the fibres in the human brain, made under the direction of Professor Aeby, by F. Buechi, of Berne, Switzerland; a set of anthropometric apparatus and instruments similar to that shown in the Health Exhibition in London in 1884, and devised by Mr. Francis Galton; a series of colored plaster casts of frozen sections of the human body, as made by Professors Braune, His, and Rauber, of Leipsic; and a series of microscopes illustrating the history of the origin and development of this instrument. Facts regarding the library we have already given.

An English Medical Journal suspends Publication.—One of the four London medical weeklies, *The Medical Times and Gazette*, suspended publication at the close of the past year.

Death of Dr. John Orne Green.—Dr. John Orne Green, of Lowell, Mass., died on Saturday, December 26th, at the age of eighty-seven years. He was the author of a number of valuable medical papers, among which were "A History of Small-pox in Lowell, "Biography of Calvin Thomas, M.D," "Cases of Fracture of the Liver," "Memorial of John C. Dalton, M.D.," and "The Factory System in its Hygienic Relations."

Spontaneous Hydrophobia.—Dr. Dujardin-Beaumetz has read before the Hygienic Society a paper on what he regards as a well-established case of "spontaneous hydro-

phobia" in a man aged twenty-nine. Not only did all the symptoms which characterize that malady declare themselves, but the matter taken from the patient's body when he died communicated it to rabbits inoculated therewith. The patient declared on entering the Hôtel Dieu that he had not been bitten or scratched by a dog or any other animal, nor been in any sort of contact with one. The body was minutely examined before and after death, and the skin was everywhere intact.

Correction in Dr. Van Santvoord's Case before the Pathological Society.—In the report of the proceedings of the New York Pathological Society, which appeared in The Record for December 26, 1885, Dr. Van Santvoord, in the presentation of a carcinomatous uterus, should have been recorded as saying: "That the woman was attended by a midwife, in the capacity of physician, until three days before death, the midwife treating the woman for a 'blood cancer.'" There was no question of pregnancy in the case at all.

Laryngological Section of New York Academy of Medicine.—A meeting called for the organization of a Laryngological Section of the New York Academy of Medicine was held in the rooms of the Academy, on the evening of December 23, 1885, the President of the Academy occupying the chair. A valuable paper, entitled "The Surgical Uses of Electricity in the Upper Air-passages," was read by Dr. R. P. Lincoln, and was followed by a discussion. Dr. Rufus P. Lincoln was elected President, and Dr. D. Bryson Delavan Secretary of the Section for the ensuing year, and a general plan of organization adopted. The interest in the Section manifested by the members present gave gratifying assurance to its future success.

Blackwater Fever.—Dr. J. Farrell Easmon, of Accra, Gold Coast, West Africa, under date of November 9, 1885, writes: "In page 289 of your issue of September 12th, you quote a review of my pamphlet on blackwater fever from the London *Medical Record* of July 15th. My name is not Dr. Farrell, as you have it in your quotation, but Dr. J. Farrell Easmon."

Missionary Physicians in the East.—Dr. Allen's letter on this subject in our December 12th issue has called forth many inquiries from correspondents. We are unable to give any further information than that contained in the communication referred to. Such of our medical friends as desire more should communicate with the missionary boards of their respective religious denominations.

A Professional Pretender.—Graduates of the Medical Department of the University of New York are cautioned against one Dr. F. W. Cowan, who is, under the pretence of being robbed, etc., borrowing money from members of the profession. Dr. H. C. Cooper, Clerk of the University, would be pleased to receive the names of those who have already been victimized.

Successful Vaccination after Small-pox.—Dr. E. D. Powers, of Lafayette, Ind., writes: "Having read the cases of successful vaccination after small-pox in the December 19, 1885, issue of The Medical Record, I am tempted to relate my case. My wife and her brother had the small-pox when young children, both sick at the same time. The brother's face is very badly marked, my wife's not so badly. So there is no doubt as to the nature of the attack in her case. My son, fifteen years of age, having found a point that had been used, playfully insisted on vaccinating his mother, and did so. The vaccination was successful, and ran through a typical course, very much to our surprise, as we considered her perfectly safe."

The Doctor and the State.—Dr. Adolph Rupp, of this city, sends us some criticisms upon our editorial regarding the working of laws regulating medical practice. And he asks: "Are you not giving the State too much power, and in a State, too, where the existing laws regulating medical practice have been adjudged by the court as being as absurd as they are unjust?" It should be remembered that we have not defended present medical laws, but only the principle involved in making them; also, that laws regulating medical practice have very little to do with the doctor after he has become legally registered. Their aim is, or should be, to see that the State is supplied with educated physicians, not quacks. They alone require of the doctor very trivial services to the State, and they do not abridge his liberty more than that of other responsible citizens.

Northwestern Medical and Surgical Society, New York.—At the regular Annual Meeting of the Northwestern Medical and Surgical Society, held on December 16th, the following officers were elected for the ensuing year: Dr. J. H. Fruitnight, President; Dr. R. C. M. Page, Vice-President; Dr. S. Newton Leo, Secretary and Treasurer. From the reports presented by the various committees it was evidenced that the Society was in a very prosperous condition.

Maternity Hospital, New York.—Dr. Egbert H. Grandin has been appointed Obstetric Surgeon to the Maternity Hospital, *vice* Dr. P. F. Mundé resigned.

A Hydrophobia Association has been organized in London. Its objects are to check the great increase in the number of deaths from hydrophobia which has lately taken place. 1. To enforce existing laws as to the capture and destruction of stray and ownerless dogs. 2. To move Parliament for further legislation in reference to dogs, by an increase of the dog tax, and by making it compulsory to have the name and address of the owner on every dog's collar, and a ticket denoting that the tax has been paid. 3. To obtain all possible information on the cause, symptoms, and treatment of the disease, and to make the conclusions arrived at known to the public. 4. To take all such steps as may be considered necessary to further the objects of the Association.

Injunction Denied against the Medical Society of the County of New York.—Albin Fulda, having brought an action against The New York County Medical Society asking that defendant be enjoined from instituting proceedings against plaintiff, under L. 1880, ch. 513, and section 356 of the Penal Code, forbidding any one to practise physic without authority, etc., obtained an order to show cause why defendant should not be so enjoined. After hearing the cause, Judge O'Gorman, last week, at Special Term of the Superior Court,

held that the case was not one in which an injunction should issue. On the moving papers it appeared that the actions instituted by the Society were to recover penalties. The answering affidavits showed, however, that on November 6th, Fulda had been convicted in General Sessions of a misdemeanor in practising physic contrary to the statute, and had appealed because, among other grounds, the Recorder ruled that the People in such prosecutions might rest their case on proving practice, and shift to defendant the burden of proving authority so to do (following People *v.* Nyce, N. Y. Crim. Reps., vol. iii., p. 150). The purpose of the injunction, therefore, was to prevent the Society from complaining of similar breaches of the criminal law.

This case has deservedly attracted attention, and Judge O'Gorman's decision is calculated to sustain a sound and wholesome rule. It appeared on the hearing that the plaintiff claimed to have received a medical diploma from a college in Halle, in Prussia, which diploma he had lost. Having had sufficient time to obtain from this college some verification of his statement, he failed to do so, when it would have been important to his defence in the criminal action which had been brought against him, and in which he was convicted of practising the profession of a physician without license. The general principle upon which Judge O'Gorman put his ruling was that a court of equity, in the exercise of a sound discretion, ought not, unless in the protection of a suitor from clear, manifest, and irreparable injury, to use its great power by injunction to stay proceedings of public officers, acting in good faith, under competent authority, in arrest of persons accused of violation of law. On this subject the learned Judge adverted to Davis *v.* American, etc. (75 N. Y., 369), and cases reported in 12 Abb. N. C., 436 et seq. The wholesomeness of the application of this principle to suits brought to enjoin the enforcement of the medical qualification and registry laws is obvious, in view of the great danger to the public from allowing men to practise medicine without due evidence of their proper preliminary education. There can be no doubt that, inconvenient as such regulations sometimes are to practitioners and those desiring to become practitioners, they are in the long run greatly to the advantage of the practitioners of medicine as well as to the public at large. Whatever raises the standard of professional qualifications inevitably improves the position as well as the usefulness of the profession, and the records of the law bear witness so frequently to the criminality of incapacity that the enforcement of restrictive regulation is a matter for congratulation.—*The Daily Register.*

A Compliment to an American Physician.—At the next meeting of the British Medical Association, at Brighton, the address in medicine will be delivered by Dr. Austin Flint. Of him the *British Medical Journal* says: "Dr. Austin Flint holds a position of recognized eminence and seniority in America, and has filled with honor the highest professional offices in his country. He is well known at the meetings of our Association, and has won for himself universal esteem and friendship. He is an admirable type of a class of American physicians, and, while retaining the national characteristics, is distinguished for cosmopolitan culture and calmness of judgment."

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 28, 1885.

Daniel Lewis, M.D., President, in the Chair.

The *Comitia Minora* reported, in

THE CASE OF BROWN *vs.* FIELD,

that nearly five thousand dollars had been pledged toward an indemnity fund, to be used if necessary in defraying the expense of further legal proceedings incident to an appeal.

Dr. J. Leonard Corning read a paper in which he described his method of producing

PROLONGED ANÆSTHETIZATION BY INCARCERATION OF THE ANÆSTHETIC FLUID IN THE FIELD OF OPERATION,

and exhibited the apparatus used for accomplishing this purpose. As injection into veins is not desirable, he adopts the precautionary measure of mapping them out with a blue crayon pencil after the circulation has been interrupted in the superficial veins by an elastic bandage. The next step consists in exsanguinating the limb with the Esmarch bandage, making a long fold behind the points of injection, and the application of this should cease when the lower boundary of the field of operation has been reached. The injections should be made after the application of the Esmarch bandage, and just above its border. First make superficial injections of a one or two per cent. solution of cocaine, and as soon as anæsthesia of the skin is accomplished, proceed to anæsthetize the deeper parts by injecting the tissues with a one or two per cent. solution by means of long needles. *The greater the extent of operation the weaker must be the solution used.* Make the injections as rapidly as possible, which should not occupy more than four or five minutes. Then apply a tourniquet a short distance above the upper border of the anæsthetic zone. The best tourniquet is an india-rubber band, three inches long and two inches wide, secured in place by a powerful clamp. Supplementary injections may be required, which can be made as rapidly as possible *after loosening* the tourniquet, and, when done, again tightening it. A complete description of this ingenious method will soon appear in a monograph.

The President cited a case which he regarded as a very good test of the value of Dr. Corning's method. It was one of recurrent epithelioma situated over the left shoulder-blade, and the incision for its removal was three and a half inches in length. The integument proved to be not less than one-fourth of an inch thick, and yet the patient went through the operation without complaint. Only one application of cocaine was made.

Dr. Milton Josiah Roberts regarded the technique of the method as essential, and the details should be carefully observed. He had adopted Dr. Corning's method satisfactorily in exsection of the elbow- and hip-joint, in osteotomies, scraping extensive abscesses in connection with bone disease, etc.

Dr. Paul F. Mundé then read a paper on

THE TREATMENT OF PELVIC ABSCESS IN WOMEN BY INCISION AND DRAINAGE.

By far the larger proportion of cases of pelvic peritonitis and cellulitis terminate in a gradual absorption and ultimate complete disappearance of the exudation, leaving either no traces whatever, or merely a more or less limited mobility of the uterus, or a vague fulness of the parametrium. This process of absorption may extend over months, and even years, severely taxing the endurance of the patient and the resources of the physician.

The rapid breaking down of the exudation and the formation of an abscess is comparatively rare, and may be considered decidedly the exception. It is most liable to occur when the exudation has formed very rapidly and is very large, and when the recuperative powers of the patient are below par. Suppuration occurs by far more frequently in cellulitic exudations than in those caused by pelvic peritonitis, and is most commonly met with when the cellulitis comes on after parturition at term or after an abortion. In cellulitis it is self-evident that the exudation and, *eo ipso*, the abscess is extra-peritoneal. In peritonitis, the pus, of course, lies in the peritoneal cavity; but the rapid formation of adhesions between adjacent folds of intestines and neighboring organs and tissues closes the abscess-cavity, and separates its contents from the rest of the abdominal cavity almost as securely as when the abscess is extra-peritoneal. This point is of considerable practical importance in deciding as to the safety of tapping or incising a pelvic abscess; for, if the adhesions which shut off an intra-peritoneal abscess from the rest of the serous cavity are sufficiently firm, and if the wall of the abscess is adherent to the abdominal wall, there is no more risk in opening such an abscess than if it were actually extra-peritoneal.

Fortunately, the necessity of making the differential diagnosis between these two conditions does not often occur, since cellulitis far more frequently terminates in suppuration than peritonitis.

When I suspect suppuration in a pelvic exudation, which I do either because the swelling persists undiminished long after nature should by rights have absorbed it, or because it becomes puffy, doughy, and boggy to the touch, or because distinct fluctuation can be felt, I first proceed to verify my suspicion by the aspirator, and having discovered pus, if the quantity is presumably small, attempt to remove it all by aspiration through the vagina, where the suspicious point is usually most prominent. I have had an aspirator made, with a long metal tube provided with a stop-cock, to which tube I first attach a hypodermic syringe, and when pus is found close the stop-cock, and substitute for the hypodermic a larger syringe holding about one ounce; opening the stop-cock, I then withdraw all the pus by repeatedly filling the syringe if necessary. If there are a number of small abscesses, so-called multiple abscesses, repeated introduction of the needle may be required at different spots, in order to remove all the pus.

To insure success by this method of simple aspiration (without incision and drainage, understand), it is absolutely necessary that the abscess cavity be so small as to permit of its contracting and closing when its contents are removed.

Accordingly as a pelvic abscess points toward a spot where it can be readily reached by the knife, or opens in some inaccessible cavity, such as high in the rectum or in the bladder, is the operative treatment easy or difficult.

As a rule, the rectal perforation is situated too high up to enable it to be reached and enlarged. Such patients may carry their abscesses about with them for years, and experience comparatively little discomfort from them, except the occasional purulent evacuations from the rectum.

If the abscess happened to burst into the bladder, it is even less easy to reach, and our efforts are almost wholly restricted to irrigating the bladder and preventing that viscus from catarrhal inflammation. This variety of pelvic abscess usually heals soon, because natural drainage is better provided for than in rectal perforation.

When the abscess opens through the vaginal roof, generally to one side or behind the cervix, drainage is mostly so perfect that, as the exudation is absorbed, the abscess cavity also contracts and closes. A necessary condition for this happy termination is that the opening remains sufficiently large to permit free drainage.

Some pelvic exudations extend not only down into the pelvic cavity (I have seen them in the recto-vaginal septum nearly down to the perineum), but also work their way over to the iliac fossa and into the supra-peritoneal cellular tissue of the anterior abdominal wall, dissecting off the peritoneum from the ileum and anterior pelvic wall, and forming a hard, brawny swelling, apparently immediately under the skin of the hypogastrium. Such exudations are rather prone to suppurate, and the pus will then usually point toward some spot to the side of the median line, toward the crest of the ileum.

The indication in these cases obviously is to follow the old surgical rule and give exit to the pus as soon as, and where it can be most distinctly felt, whether this be in the abdominal region or in the vagina.

If a soft, boggy, more or less fluctuating spot can be detected in the abdominal exudation, an aspirator or exploring needle should be thrust into it, and if pus is found, a grooved director should be inserted, and the abscess thoroughly opened with a blunt-pointed bistoury. All sinuses should be explored with the probe or finger, and thoroughly opened.

If the pus has burrowed deep down into the pelvic cavity, so that a probe passed to the bottom of the abscess can be felt through the vaginal vault, the abdominal incision alone will usually not suffice, since perfect drainage will be next to impossible, and pus will almost surely remain hidden in pelvic sinuses and retard closure of the abscess. Hence it is imperative to make a counter-opening in the vaginal vault, and to keep it open it is necessary to pass a drainage-tube through from the abdominal incision into the vagina and retain it there until the gradual closure of the abscess calls for its substitution by a smaller one, and ultimate removal.

Dr. W. M. Polk, at a recent meeting of the New York Obstetrical Society, reported a case of a suspected small abscess deep in the pelvic cavity opposite the ischiatic spine, in which fluctuation could not be detected through the vagina. Feeling sure that deep-seated pus existed, he cut down from the abdominal wall, pushed up the peritoneum, found the abscess by the aspirator, opened and drained it, and the patient recovered. It is seldom necessary, and not often thought safe, to cut down on such deep-seated accumulations of pus in the pelvic cavity; indeed, they can almost always be more easily reached through the vagina. And it would seem that vaginal drainage would be preferable, in such cases, to the abdominal exit chosen by Dr. Polk.

Intra-peritoneal abscesses are fortunately not so common as those in the cellular tissue of the pelvis and abdominal walls. And in the former, adhesions between the intestines and the abdominal wall are often so dense as to render the abscess practically extra-peritoneal. When the abscess then points through the abdominal wall, its incision, while really a laparotomy, does not open the free abdominal cavity, and is usually no more dangerous than that of a simple pelvo-parietal abscess. Of course, care must be observed not to break down the adhesions and open the healthy peritoneal cavity.

The mistake of calling the incision of a pelvic abscess which points through the abdominal walls a "laparotomy" appears to have been made by various authors and speakers.

Dr. Mundé's paper contained the histories of ten cases, at the end of which the author gave the following conclusions:

1. Pelvic abscess in the female is not very common, in proportion to the great frequency of pelvic exudations, and probably does not occur in more than ten per cent. of all cases, the majority of exudations terminating in spontaneous absorption.

2. Pelvic abscess may be either extra-peritoneal, the result of cellulitis (by far the most common variety), or intra-peritoneal, the consequence of pelvic peritonitis. If intra-peritoneal, the adhesive inflammation between pelvic viscera and intestines may so seal the abscess-cavity as to render it *practically extra*-peritoneal.

Abscess of the ovary and pyo-salpinx do not belong

in the category of "pelvic abscess" proper, and do not fall under the same therapeutic rules, unless when, by agglutination to the abdominal wall or to Douglas' pouch, they become virtually extra-peritoneal.

3. Small deep-seated pelvic abscess, not exceeding a capacity of two ounces, and minute multiple abscesses in the cellular tissue can often be permanently cured by evacuating the pus thoroughly with the aspirator. The surrounding exudation is then rapidly absorbed.

4. About one-half of the abscesses open spontaneously into the vagina, rectum, bladder, or through the abdominal wall and ischiatic fossa. These cases may gradually recover without treatment, or the sinuses may persist until closed by surgical interference.

5. Abscesses containing more than two ounces of pus should be opened by free incision along an exploring needle or grooved director, cleared of débris by finger or blunt curette, and drained and irrigated, if necessary, through a drainage-tube.

6. This incision should be made at the spot where the pus points most distinctly, which is usually the vaginal vault.

7. In a certain number of cases the pus points through the abdominal wall, generally in the iliac fossa, and the incision should then be ample, and free drainage should be secured.

8. When the pus has burrowed deep into the pelvic cavity, and a probe can be passed from the abdominal incision down to the vaginal roof, mere abdomino-cutaneous drainage will not suffice, and a counter-opening must be made in the vagina, and a drainage-tube carried through from the abdominal wound into the vagina. This drainage-tube may have to be worn for months. In making this incision, care should be taken not to wound the bladder.

9. The opening of a pelvic abscess which points through the abdominal wall does not differ from, and is no more dangerous than, the same operation elsewhere on the cutaneous surface of the body. It is not an "abdominal section" or a "laparotomy," in the sense that those terms are now used to indicate the surgical opening of the peritoneal cavity.

10. Chronic pelvic abscesses, which have burst spontaneously, and have discharged through the vagina, rectum, or elsewhere for months or years, are exceedingly difficult to cure. This is particularly the case when the opening is high up in the rectum. A counter-opening in the vagina, or enlarging the opening if there situated, the curette, stimulant irrigation, etc., may occasionally succeed, but usually fail.

11. A perityphlitic abscess may point through the abdominal wall, and simulate a pelvic abscess proper. Aspiration will settle the diagnosis; the treatment is the same.

12. The majority of cases of pelvic abscess recover; at least the mortality is small.

Dr. W. M. Polk presumed that all had been very much interested in the paper of the evening, especially as it formulated a number of very well-known rules, which we should never decline to receive, particularly when they came from a source so well able to impress us with their importance.

First a few words concerning the criticism entered on his own case. Dr. Mundé had expressed the thought that the case was one in which the pus might properly have been reached through the vaginal roof. Dr. Polk only wished that Dr. Mundé had been there to try it, for he tried his best, and so did the other gentlemen who were present; but the conditions were such as made it utterly impossible to do so without making an incision, which would have jeopardized the life of the woman. The abscess was located immediately in front of the rectum, and immediately behind the broad ligament, and there was no opening between the abscess and the vaginal roof. In fact, until the patient was anæsthetized, he was not at all sure that there was an accumulation of pus in the pelvis. Therefore he performed the operation he did, making a section as for ligation of the common iliac artery, separated the peritoneum from the sides of the pelvis as far down as the middle of the sacro-sciatic foramen, put in a drainage-tube, and the patient had done well.

Since the operation an abscess has opened into the original one, and now free drainage exists without entering the peritoneal cavity. He did not perform laparotomy for the reason that the abscess was situated deep in the pelvis, without any communication with the vagina, was limited in extent, and if he had opened the peritoneum he would have simply given access to that cavity, which would have been exceedingly dangerous.

It should be understood, however, that wherever the abscess can be reached through the vagina, unquestionably that is the direction from which it should be approached.

With reference to pelvic abscesses in general, the entire question had been gone over more or less thoroughly for ten or fifteen years, and he had hoped that Dr. Mundé would bring forward some new ideas with regard to the method of meeting this very difficult pathological process. He said this with all respect, because the author of the paper was so thoroughly posted in all gynecological subjects that he had come feeling that we were going to have a broader field opened up than had been presented.

So far as mortality was concerned, his experience did not agree with that of Dr. Mundé.

The general question was simply, not whether we should evacuate purulent collections in the pelvic cavity because all agreed on that point, but it was as to the propriety of opening the abdominal cavity for the purpose of establishing free drainage in obstinate cases of pelvic abscess. Dr. Polk thought that in many cases this method offered the best chance of saving the patient's life. One difficulty was, that many would hesitate to open the abdominal cavity in the beginning of these cases, and in the meantime sepsis has developed, with the depression which attends it. But even then he thought he should be disposed to make a section through the abdominal walls, to determine what was there, if no more than an exploratory incision, trusting to finding a condition of things which could be removed.

Perhaps it would prove to be a case of pyo-salpinx, and if so, abdominal section was the proper method of treatment. If an abscess, it would be a condition of things which would permit the operator to clear out the abdominal cavity and introduce drainage. This refers solely to those cases of obscure abscess which are situated deeply, and which cannot be thoroughly drained through the vagina, and in which, unless the pus is gotten rid of thoroughly, the patient will die. Dr. Polk then narrated a case as a representative of a class.

Dr. W. T. Lusk said that what he had to add was chiefly a matter of ancient history, which meant ten years' experience in connection with this subject. When he began work in Bellevue Hospital, in 1871, the obstetric service overshadowed the gynecological service, and the cases sent there were chiefly those of pelvic cellulitis and abortion. The cases of pelvic abscess were very severe, and at that time, strange though it might seem, there were but few practitioners who could diagnosticate this condition. He did not, at that time, know that when a large collection of pus was recognizable, any harm would come from making a large free incision and letting it out; and whenever he found fluctuation above the symphysis pubis with reddening of the skin, he assumed that the tumor was adherent to the abdominal walls, and that it was only necessary to make a sufficiently large incision to remove the patient from danger at once. He had never seen any serious symptoms when these abscesses had been opened *freely;* all the patients got well, and he did not believe that if the incision was made large enough originally it was necessary to establish drainage from the vaginal cul-de-sac. If pus is found by aspiration, make an incision, three or four

inches long if necessary, empty the sac, fill the cavity with oakum, pour in Peruvian balsam when the granulations are flabby, and the cavity soon fills up.

But there are cases in which it is necessary to pass a tube up through the vaginal cul-de-sac. Dr. Lusk then spoke of the first case which he saw treated in this manner. The consultation, consisting of Drs. Barker, S. B. Ward (now of Albany), and himself, disapproved of the method as it had been suggested by Dr. C. A. Leale, to which Dr. Leale said, "Then I would be happy to have you stay and look on." Dr. Lusk assisted. The exit into the vagina was found, the sinus was followed up and opened, and a drainage-tube was introduced. Within one month the patient was well, after having suffered *nine* years from pelvic abscess which communicated with the large intestine, and also opened into the vagina.

Dr. Lusk referred to a case in which a good man treated a pelvic abscess as a fibroid tumor for two years; the patient was cured by the drainage-tube in a short time. He also referred to *two* cases which illustrated the possibility of confounding ovarian cyst and pelvic abscess, and in both the patients were quickly cured by removal of pus through the vaginal cul-de-sac.

Dr. W. Gill Wylie could agree with a good deal of Dr. Mundé's paper, but there were some points on which he held different views. In the first place, very many of the cases which Dr. Mundé would call cellulitis, he would call pelvic peritonitis.

Again, he thought that probably four-fifths of the cases of pelvic abscess were really culminations of disease of the Fallopian tubes. There is first inflammation in the posterior layer of the broad ligament, lymph is thrown out, contraction ensues, the tube is rolled backward, both tubes and ovary are in a measure cut off from the general cavity of the peritoneum, and in this rolled-up tissue the great majority of so-called pelvic abscesses begin.

He had adopted this view within the last three or four years, and it had come from observations made in laparotomies.

He thought that Dr. Mundé had laid too little stress on the dangers of even puncturing with an aspirator in the vagina. He doubted whether he should ever attempt to puncture an abscess holding more than two ounces in the pelvic cavity, unless a mere phlegmon with boggy tissue and pointed. He regarded free drainage as the proper treatment, of course, as Dr. Mundé had stated, and he would first perform it through the vagina, but if that failed he would resort to other measures. His method of establishing this drainage is to introduce an aspirator-needle, dilate the puncture, and then insert a drainage-tube.

Dr. Irwin referred to a case of acute pelvic abscess in which he advised opening at once, but the circumstances surrounding the consultation were such as rendered it especially desirable to postpone for twelve hours, and in the meantime rupture occurred into the bladder. The patient recovered after a tedious illness. Dr. Irwin thought that the case illustrated the principle that the pus of acute inflammation should be evacuated at once, which might avoid long and painful illness.

Dr. Putnam-Jacobi thought it of great importance to have it laid down at what time after the subsidence of acute inflammation the operation should be performed. She cited a case in which she urged a prominent gynecologist to aspirate a pelvic mass which remained after an acute inflammation had subsided, with the view to the probable removal of a small quantity of pus, and thus prevent perforation somewhere else. He finally consented, and did draw off about a drachm of pus; but within a week there was a discharge of pus from the bladder, which was repeated three or four times. The patient recovered from the acute attack with an exudation which disappeared only after two years. The question is whether the irritation caused by the attempt to relieve the patient did not facilitate suppuration and ulceration into the bladder, which otherwise might have been averted.

Dr. Fruitnight related a case in which pelvic cellulitis was followed by abscess, with perforation into the rectum, and in which Dr. Leale established free drainage through the vagina. The patient wore the tube for four months, and is now well.

Dr. Mundé, in closing the discussion, was very much obliged for the response made to his invitation to discuss his paper. He would like, however, to take exception to the criticism that his paper contained nothing new, and desired to say that he did not claim that it did. He did not write it for that purpose, but invited his distinguished hearers to discuss it for the purpose of hearing from them something new, and he had had the pleasure of hearing several things.

As to the statement made by Dr. Wylie, that the great majority of cases of pelvic abscess are cases of pyo-salpinx, he did not believe that he should ever agree with him on that point.

He agreed with Dr. Polk that there was danger in opening abscesses through the vagina, because of the danger of opening the uterine arteries, and he had omitted to mention the fact in his paper. He had brought the subject before the Society because he wished to bring out a number of points in connection with these cases, and to especially make prominent the fact that they can be operated upon as easily as abscesses elsewhere, with certain precautions taken into consideration.

The first three gentlemen who participated in the discussion had wandered from the subject, as intra-peritoneal abscess did not come into consideration in his paper. He agreed with them as to the treatment proper for pyo-salpinx when it is loose in the pelvis. He had also thought it important to point out the difference between laparotomy and opening of the abdominal walls.

THE CROTON WATER SUPPLY.

Dr. John C. Peters, from the Committee on Hygiene, made a verbal report on the question of increased water-supply for the city of New York, and pointed out the advantages claimed for the Quaker Bridge Dam, and those which would follow the construction of the Sodom Dam, which could be built at much less cost and be made available within a much less period of time.

Dr. Atruzzo raised the question,

WHY SHOULD THE INDORSEMENT OF BELLEVUE HOSPITAL MEDICAL COLLEGE

protect illegally qualified practitioners of medicine? and promised to ventilate the subject more fully. No action was taken by the Society.

The Society then adjourned.

The Mental Symptoms of Aortic Regurgitation.—Dr. Douty contributes a few notes with regard to the relations between heart-lesions and certain forms of insanity (*The Lancet*). The author records fourteen cases met with in the Worcester Asylum, in which there was incompetence of the aortic valves. Of these, eleven were cases of mania, one of dementia, one of dementia with general paralysis, and one of melancholia. Of these eleven cases of mania, seven possessed very marked auditory and visual hallucinations; and from the author's observations he thinks it probable that, when fuller statistics are collected upon this subject, we shall arrive at the conclusion that the typical mental symptom of aortic regurgitation is a delusional mania, coupled with a condition of extreme instability of temperament. As surely as one discovers an aortic regurgitant bruit, almost so surely is one told by the attendant that the patient has an obstinate and irritable temper. Another very common accompaniment of this valvular lesion is the prevalence of hallucinations. Out of the fourteen cases recorded not one recovered. Rest may cause improvement for a time, but relapses always occur, and the patients never fully recover.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Stated Meeting, December 14, 1885.

STEPHEN SMITH, M.D., CHAIRMAN.

THE INDICATIONS FOR LAPAROTOMY IN PENETRATING WOUNDS OF THE ABDOMEN.

IN presenting the subject for discussion, THE CHAIRMAN remarked that penetrating wounds of the abdomen were of such frequent occurrence, especially in hospital practice, that they have a peculiar interest to the surgeon. The first question that confronts him is as to the extent and nature of the injury to the viscera of the abdomen, and it is generally exceedingly difficult to determine that question by the symptoms present. Even if he is satisfied that the viscera are wounded, he cannot decide as to the severity of the injuries and whether they call for operative interference. These difficulties grow out of the variable character of the symptoms which these injuries present in different cases and conditions, and the impossibility of deciding from the symptoms how amenable to treatment the lesions may be. It is a fact well recognized that cases recover in which the symptoms are of the most dangerous character, and, again, cases prove fatal in which the symptoms are very slight. Every surgeon treating these wounds has felt an almost irresistible impulse to open the cavity of the abdomen, and settle at once the question as to the exact nature of the lesions by ocular inspection, and proceed accordingly. Delay has seemed to him likely to prove fatal, and yet he has hesitated, owing to the perhaps greater danger of the operation than the injury. Recent experience has, however, proved that laparotomy, as an exploratory operation, is by no means as dangerous as has heretofore been believed, provided it is performed with proper precautions. If, indeed, an exploratory operation may thus be performed with impunity, one great obstacle to the successful treatment of these wounds is removed. We are favored this evening with the presence of surgeons of different hospitals, and of gynecologists of large experience, and it can but prove interesting and profitable to listen to their statements and opinions. He called upon Dr. J. D. Bryant, of Bellevue Hospital, to open the discussion.

DR. JOSEPH D. BRYANT said that the statement that "laparotomy should be performed in all cases immediately after the accident" embodied the important part of the question before the Section. He could not advocate the sentiment contained in the statement. It could not be said that it had yet been accepted by the general profession.

Conservatism was especially necessary in the advocacy of an operation the propriety of which, as yet, was surrounded by doubt. Marked advancements have been made in abdominal and general surgery, but it cannot yet be proclaimed that "laparotomy in all cases should be performed immediately after the occurrence of the accident." Few, indeed, were the hospitals that possessed the facilities necessary to the proper performance of the operation immediately.

With the permission of the Chairman, Dr. Bryant would transfer the words of the statement so that it would read, "Should laparotomy be performed in all cases immediately after the accident?" This question practically embodies three others:

First, should laparotomy be performed in any case? *second*, should laparotomy be performed in all cases? and, *third*, when contemplated, should it be performed immediately after the accident?

Ovariotomy and laparotomy for other conditions in the female are accepted operations. There is no proof that the peritoneum of the male is less tolerant of manipulation than that of the female. The length of time occupied, and the extent of raw surfaces made in many of the successful operations for conditions within the abdominal cavity, removes objections in this direction against operative interference in penetrating wounds of the abdomen.

The practical points to be considered in a case of penetrating abdominal wound that do not exert an equal influence in laparotomy for other common diseases are:

First, doubt whether the abdominal viscera have been injured. An exploratory laparotomy will enable the operator to answer this question.

Second, existing shock. This element is almost entirely limited to those cases in which laparotomy is proposed for penetrating wounds. Slight shock is always present. He believed, however, that it had been established that when severe shock followed immediately after the injury, it was due, in the great majority of cases, to loss of blood. If due to loss of blood that loss should be checked at once, and exploratory laparotomy will decide this question.

Third, unfavorable surroundings of the patient. This, like the second, was limited to laparotomy for penetrating wounds.

Fourth, unskilled operators, by which was meant that the attending surgeon may not have had his attention *forcibly* directed to the details of the operation. This obstacle can be readily overcome.

Fifth, greater exposure of the abdominal cavity and its contents. The great caution necessary in finding and removing from the abdominal cavity all the blood and extravasated intestinal matter, to check hemorrhage, and also to detect all points of injury, requires a thorough examination of the intestines and the omentum according to a preconceived method, rather than with roughness associated with haste. Time should not be considered; but care and completeness should be the determining factors in every case.

Sixth, existence of hemorrhage. In visceral perforation intra-abdominal hemorrhage is necessarily a constant feature. The suspicion of the existence of such hemorrhage is sufficient to indicate an exploratory incision.

Seventh, extravasation of intestinal contents. This is a part of the history of penetrating abdominal wounds, and is not to be dreaded by surgeons. Fecal and urinary extravasations constitute the strongest indications for laparotomy.

Eighth, the greater difficulty of cleansing the abdominal cavity. It is more tedious and difficult than under other circumstances, but of greater importance than in laparotomy under other circumstances. Its thorough performance, especially with reference to intestinal contents, appears to be the only means of saving the life of the patient.

Dr. Bryant believed that laparotomy was a justifiable operation, but that it should not be attempted, even in so-called favorable cases, unless the operator could avail himself of many of the recognized means of procedure necessary to combat the shock of the operation, and was sufficiently familiar with its steps to operate with accuracy and despatch.

Second, should laparotomy be performed in all cases? This question had been allotted to others to discuss.

Third, when contemplated, should it be done immediately after the accident? All things being equal, it should be performed at once; that is, as soon as the necessary preparations can be made.

Dr. Bryant believed that laparotomy should be of two kinds, exploratory and actual.

Among the common causes of death from penetrating abdominal wounds are hemorrhage, peritonitis, septicæmia, exhaustion, etc. Blood and intestinal contents can be recognized through the exploratory opening.

Does the explorative incision expose the patient to unusual danger? He thought not. It seemed to him that surgical experience answered the question in the negative.

Dr. Robert F. Weir remarked that in respect to penetrating stab wounds of the abdominal cavity a mere expectant plan of treatment could be followed, as the slighter impetus of a knife would more likely permit of the intestine escaping injury than when the belly was invaded by a bullet. This fact was well shown long prior to the experiments of Parkes by those of Hoyne, who in refuting, in 1865, the advice given by Legouest in gunshot wounds of the abdomen, to "enlarge the wound and draw out the adjacent intestine with the finger, and sew up the opening if thus found," showed, by shooting with a revolver of thirty two calibre into cadavers at a distance varying from three hundred and seven paces, that in eighteen bodies there were ninety wounds of the intestines produced, and that in only two instances were the bowels uninjured. We must expect, therefore, in penetrating gunshot wounds of the abdomen, to have numerous visceral injuries. In Bull's successful case there were seven openings in the intestines, and in Hamilton's eleven. In the experiments of Hoyne the greatest number found in one cadaver was ten, but Longmore gives a case where a wound received by a man when defecating perforated the bowels sixteen times. While perhaps some variation from the severity of the injury made by a ball may be found in battle, yet in the close-range shooting that so frequently sends patients to a civil hospital the determination of the simple question of the penetration or non-penetration of the abdominal cavity by a ball is all important. This is better done by the enlargement of the wound and the introduction of the finger, though sufficient information may in many instances be obtained by the probe. But clinically it is found that every case of such a wound does not justify a laparotomy. When such a patient comes under the eye of a surgeon, the collapse in which he or she is in may, and too often does, prohibit utterly surgical interference. In only one condition is there an operation justifiable, and that is for the arrest of the hemorrhage which may be the cause of the shock. To determine this so difficult question, Dr. Weir suggests a small incision, under cocaine or without an æsthetic, be made in the median line, or that the wound of a direct one be enlarged and a sponge on a stick be thrust down to the pelvis or into the lumbar gutters. Its state on withdrawal will at once decide the question—if no bleeding has occurred, the wound can be closed, and a better condition of the patient awaited for, to undertake the more important act of exploring for wounded viscera.

Where the general condition of the patient warranted, he was strongly in favor of laparotomy in the treatment of these cases of gunshot injury. In addition to the successful cases already referred to, there was another of gunshot wound reported in Demarara, where the bullet was found by laparotomy imbedded in the liver, whence it was satisfactorily extracted. In such operations not only should antisepsis be rigidly carried out, but a rather large abdominal section should be made, so that the intestines could be rapidly handled, either by turning them out of the peritoneal cavity, which is the most certain, but probably the more dangerous, plan, or by passing the coils between the fingers and keeping them in the abdominal cavity. The former plan has the weight of the authority of Treves in its favor.

It is admitted to be an operation of great risk, but, done for an injury, nearly always fatal. However, it seems that those cases in which fæces readily escape through the wound have a better chance of recovery than where this symptom is absent. Whether more of such cases recover in this way than would after laparotomy is premature to say; indeed, the whole subject of laparotomy for gunshot wounds is so recent that he would not wish to be too dogmatic in presenting the foregoing views, and would like to maintain a reserve of judgment to be strengthened by further experience.

Dr. W. M. Polk said that he had had no experience in gunshot wounds of the abdomen, and if he made any remarks in response to the invitation of the Chairman they should relate solely to abdominal section from the standpoint of gynecology. Laparotomy for gunshot wounds was, to his mind, a more serious operation than the usual section for the removal of ovarian tumors or diseased tubes.

Save in the event of extensive adhesions, in neither of these conditions was it necessary to disturb the intestines or other viscera to any extent. The time usually at our disposal in which we studied the cases gave us in many instances a fair idea of the relations of the growth to be removed. This in itself was a great advantage.

When one looked back at the operations but recently performed for the removal, for instance, of the tubes and ovaries, and contrasted the results as then obtained with those now had, some light might be thrown on the causes which made operations for gunshot wounds of the intestines more dangerous than operations for the removal of bodies whose position could in a measure be determined beforehand.

Formerly it was the custom with many operators, in case adhesions were found, to consume much time in separating them; if there was even oozing, the intestines, which had already been much disturbed, were lifted from the pelvis, pushed up into the abdominal cavity, or were laid out on the abdominal surface; every bleeding point was scrupulously stanched, sometimes even by the use of powerful hæmostatics; in fact, the peritoneal surfaces, visceral and parietal, were much handled and exposed. As a result these cases often died. Such, in fact, was the mortality that every one shrank from the operation. The idea prevailed, as in a measure accounting for the mortality, that the virgin peritoneum was a specially inflammable tissue, and old cases, cases which had been the victims of one or more attacks of peritonitis, were considered the more favorable. Some maintained that the American women were more prone to the cause of death appertaining to abdominal section.

With the introduction of better methods of operating, these ideas had been abandoned as the mortality had lessened. For this advance we were indebted to Mr. Tait. Now we made small incisions, if possible, we went directly down into the pelvis, and in the removal of the tubes and ovaries did, in nearly all cases, our work by the sense of touch. Adhesions were torn up, and, unless there was something more than general oozing, we put in a drainage-tube, with the assurance that the bleeding would soon cease. There was very little exposure of the peritoneum, and very little handling of the viscera.

Now, these conditions might even be present in the removal of tumors of large size, for the intestines in such cases were pushed well aside by the growth; and owing to the improvement in the conduct of such cases adhesions were becoming less common, certainly less extensive; consequently less excuse for exposing and handling the intestines.

If this could obtain in the operations for the relief and cure of gunshot wounds, Dr. Polk thought laparotomy for the one class of cases would be as harmless as the same operation for the other. It was for the great surgeons to say whether such could be brought about.

As to the danger of simple exploratory incisions, that would depend upon how much exploring was done. In the case of a tumor, even of considerable size, an exploratory incision would involve but little risk. As pointed out, the intestines in such cases were usually pushed well aside, back, and above, so that the hand could be carried around such growths with but little disturbance to the viscera. Supposing the case to be one of a small pelvic growth, we would carry our fingers into a territory comparatively limited.

In one whose topography was fairly fixed in our minds, as the result of previous vaginal and rectal examinations, there was but little disturbance needed to obtain positive and speedy knowledge of the conditions present. Was this possible in exploratory incisions having for their

object the determining of the damage done in cases of gunshot wounds? He thought not. The amount of handling and exposure of the viscera that would be needed to gain accurate information in cases of gunshot wounds made such an exploration more hazardous than such as fell usually to the lot of the gynecologist.

As regards the mortality of abdominal sections, Dr. Polk would cite the results obtained in the department of gynecology in Bellevue Hospital during the present year. In that department alone there had been some forty-five such sections, covering the removal of the various pelvic morbid growths, from simple ovaries and tubes to uteri, the seat of fibroid disease, and there had been but three deaths.

This, too, in a general hospital, which but a few years ago was spoken of as a pest-house. Several of Dr. Polk's operations had been done in the general amphitheatre, before several hundred students. All of these cases had made excellent recoveries.

Dr. Polk did not believe that the difference in the results now obtained in the so-called "Tait cases," as compared with those obtained a few years ago, could be set down to the presence of sepsis then and its absence now. Many of the worst results under the old method of exposure and handling had been obtained in the midst of the fiercest rage of Listerism; in fact, he was not so sure but that some of the fatal results were due to the too free use of disinfectants rather than to their absence.

We were probably no cleaner now than we were then. Then it was with the aid of disinfectants, now with the aid of boiled water and soap. But now we operated better. He did not regard a properly made exploratory incision as specially dangerous in itself.

In answer to a question from the Chairman, as to whether he considered the pelvic peritoneum more tolerant than the abdominal peritoneum, Dr. Polk replied that, to his mind, the tissue was in all essential respects the same in both regions. The fact that pelvic peritonitis was so common, that it was generally local, and so rarely fatal, was, in his opinion, a mere matter of location. Owing to the position of the patient, gravity tended to keep the offending matter at the bottom of the sac. Such was not the case when the offending material attacked the upper parts of the peritoneal sac. In the one case the conditions were generally favorable for the encapsulating of the poison by the quickly forming plastic exudation; in the other, that is, when the poison gains access above, it is constantly tending downward, and the limiting exudation is steadily encroached upon till finally it gives way. If the position of patients with pelvic peritonitis were to be reversed, so as to make that region the highest, he was disposed to think that cases of general peritonitis would as often spring from pelvic peritonitis as from peritonitis beginning elsewhere, it being understood, of course, that the poison originating the inflammation should be the same in any cases selected for comparison.

Dr. Alfred C. Post remarked that there was a great difference in the danger of abdominal wounds, depending on their situation. The danger of fecal extravasation was much greater in wounds of the umbilical zone than in those of the epigastric or hypogastric zone. Punctured wounds penetrating the stomach are much less dangerous than those which penetrate the intestinal canal. Dr. Post remembered a case to which he was called, in which a man was stabbed in the epigastric region, in which there was a protrusion of omentum at the wound, and vomiting of undigested food with a considerable quantity of blood. Perfect quiet was enjoined, with entire abstinence from food for several days, nothing being taken into the stomach but small pieces of ice. The patient recovered without any alarming symptoms.

Small wounds of the abdomen may give rise to fecal extravasation, as in a case which was presented at Dr. Post's clinic, in which a persistent fecal fistula followed the use of an aspirating needle, in the hands of a physician unknown to the reporter, designed to evacuate the urinary bladder. A small, indirect wound penetrating one of the hollow viscera is sometimes more dangerous than a large, direct one, the extravasated material in the one case being confined in the abdominal cavity, while in the other there is no obstacle to its free escape through the wound. Dr. Post related a remarkable case of recovery from a gunshot wound of the abdomen, which occurred during the draft riot in this city in the war of the rebellion. A man who had not emptied his bladder for many hours was standing on Fourth Avenue at the corner of Twenty-second Street, when he was struck in the lower part of the abdomen with a large bullet fired from a gun in the hands of a man on Third Avenue. There was a great gush of urine through the wound, and the patient was soon after seen by Professor W. H. Van Buren, who continued to attend him. The wound was so large and direct that the urine readily escaped from it, and the patient recovered without any very formidable symptoms.

Dr. Post expressed the decided opinion that in penetrating wounds of the abdomen, attended with extravasation of fæces, urine, or bile, or with copious hemorrhage, the danger is greatly diminished by laparotomy, followed by a thorough washing of those parts of the cavity which have been contaminated by contact with foreign material. He alluded to the practice of Mr. Lawson Tait, who introduces into the peritoneal cavity large quantities of warm water, lifting the viscera with his hand, and moving them so that the water may flow freely over every part of their surface.

In cases of formidable hemorrhage from abdominal wounds, the patient's safety is greatly promoted by exposing and tying the bleeding vessels.

Dr. W. Gill Wylie said, if we understood thoroughly the pathology of shock, we could better answer the questions asked. I do not altogether agree with the remarks of Dr. Polk. It is true that the older methods of doing laparotomy gave very bad results, but I am certain that it was not shock that caused death in most cases. The large openings made in the abdominal wall, and the prolonged operation, gave greater exposure to septic poisons, and the larger number of assistants increased the number of hands, instruments, etc. My opportunity for seeing others operate for the past thirteen years have been great; and I am certain that at least four-fifths of the deaths have been due to sepsis.

My opinion is that the peritoneum and intestines will stand a great deal of handling without serious results, provided we do not cause hemorrhage or infect with septic poison.

In a large experience I have come to the conclusion that, as we operate to-day, shock is to be feared chiefly in those cases where we have large vascular growths to deal with, such as vascular myomatous tumors, where a certain amount of hemorrhage cannot be avoided, and we often lose more blood than we think. Enough attention has not been paid to the direct influence of removing intra-abdominal pressure. Often the intra-abdominal tension is very great, and when we open the abdomen the immense blood-vessels of these vascular tumors fill and distend, and may thus take a pint or more of blood suddenly from the circulation. Besides, we know the capacity of the abdominal and pelvic blood-vessels and that they can hold one-third or more of all the blood, and when intra-abdominal pressure is removed they fill and distend, and in a measure thus account for the shock. When we pull on the uterus when the abdomen is open signs of shock often at once become apparent. Now we can push up the uterus by the vagina, when the abdomen is closed, and no such result is produced. I think this is due to the suction action caused by atmospheric pressure. As the uterus is lifted the immense pelvic veins fill and suddenly withdraw a certain amount of blood from the heart. A sudden withdrawal of a relatively small amount of blood will thus cause shock.

To obviate this result, I would try to force back blood into the circulation, by means of an elastic bandage, or pressure on vascular tumors, before tying the arteries that supply them with blood, and after the operation always secure even, elastic pressure over the abdomen and pelvis by means of strapping and bandaging, with a large amount of cotton-wool over the whole surface. My views are, then, avoid hemorrhage or a sudden withdrawal of blood from the general circulation and you will not often have dangerous shock from operating. Keep away septic poison by as little exposure of the peritoneum as possible, and carefully wash out of the peritoneum blood, pus, or any matter likely to cause sepsis; and to accomplish this I do not hesitate to syringe the peritoneum with one to ten thousand bichloride of mercury, or one to one hundred carbolic acid, and follow this with boiled water at a temperature of 102° or 104° F. To prevent any excess of water remaining, I usually put under the small of the back an elastic pillow, which will prevent sagging on the sides, and I then carefully sponge in Douglas' pouch. I certainly would not hesitate to open and explore in any case of wound to the peritoneum or intestines, where the life of the patient was in danger from either hemorrhage or perforation.

Dr. L. M. Bingham, University of Vermont, Burlington, was invited to participate in the discussion, and said that in cases of shock from wounds of the abdomen, or from any other source, he believed they were followed by temporary paralysis of vaso-motor nerves, and consequently there was dilatation of all the blood-vessels. He believed that the capacity of the blood-vessels in the abdominal cavity was sufficient, when dilated by shock, to contain all the blood in the body, hence, under such circumstances it was good practice to compress the abdominal viscera with firm and steady pressure, thus preventing the blood-vessels from overfilling with blood. In simple cases of syncope this pressure is followed by immediate restoration.

Dr. C. S. Wood said this was an important question and discussion, as the remarks made would be published and scattered broadcast through the land.

Should all cases of penetrating wounds of the abdominal cavity be treated by laparotomy? In reply to this it should be considered that, in our large cities, with the best of surgeons, good hospitals, all the means of antisepsis at our command, and with the patients seen early, this course may be advisable; but of the whole number of cases occurring throughout the country probably not more than one in twenty will occur where such advantages exist. Few, comparatively, of the profession are capable or qualified to perform successfully this operation; besides, they have not the necessary means at command, now considered so indispensable, to make the operation a success; therefore we should not be in haste in recommending it in all cases. There can be no question, but with our present antiseptic precautions very many valuable lives may be saved, and he often thought that had Jim Fisk received the same treatment that Dr. Bull gave his patient, he might have been alive to-day.

If he might be permitted to refer to army experience he would state that we saw a great many perforating wounds of this cavity, that we did not use antiseptics at that time, and that most of them died, even on the field where they fell, before we saw them at all. Still, some recovered, three such cases being reported by him in "The Medical and Surgical History of the War," cases where fecal discharges occurred from both the point of entrance and exit of the bullet. Other cases recovered where the cavity was opened by a piece of a shell, and portions of the omentum either sloughed or were cut away by the surgeon. For one he was disposed to be rather conservative in this as well as other operations, as shown by a paper recently read by him before one of our sister societies on the treatment of intestinal obstruction, in which he urged the use of all other means before proceeding to the severe and usually fatal operation of laparotomy.

Dr. A. C. Bernays, of St. Louis, said: I think the question must be answered in the affirmative. There is given a *perforating* wound of the abdomen, we are in ignorance as to the inward or deeper injuries. We know, and the remarks of Drs. Bryant, Polk, and Wylie confirm the fact, that explorative laparotomy is not a dangerous operation. It is evident, then, that by performing laparotomy, we do not increase the already existing danger caused by the traumatism. The operation, first, makes a diagnosis possible, and, secondly, permits us to adopt curative means. We may expect to save many lives by this operation, and I am emphatically in favor of its performance in all cases. This morning, through the kindness of Dr. Dennis, I saw a case where laparotomy was performed soon after a stab wound. The gut was found perforated in two places. Dr. F. S. Dennis stitched the wounds, replaced the bowel, and I can assure you, that the patient is perfectly well at the present time, fifteen days after the accident. In illustration of the fact that nature will sometimes achieve a cure unassisted by surgical skill, I will relate the following case, which I saw in consultation with Dr. E. Voerster, of St. Louis, some months ago. A child, about five years old, was shot in the abdomen, the ball entering just above the middle of Poupart's ligament. There was free discharge of thin fecal matter through the opening for four or five weeks. Evidently adhesions had formed and there was practically an artificial anus through which a part of the contents of the alimentary canal was discharged, another part passing off *per vias naturales*. The anus closed spontaneously, aided only by salves and perhaps some cauterizations. Had I been called early in the case I would most probably have done laparotomy. I would consider it bad practice on the part of the surgeon to refuse laparotomy in such a case, while I must admire the courage (or the blissful inactivity) displayed by the physician in this case.

Dr. George G. Hopkins, of Brooklyn, asked: Do I understand Dr. Weir to say that the exploratory incisions should always be the enlarging of the original wound?

Dr. Weir answered in the affirmative.

Dr. Hopkins: Then, Mr. Chairman, it seems to me that in comparing laparotomy for penetrating wounds with laparatomy done by abdominal surgeons, as suggested by Drs. Polk and Wylie, for the removal of ovarian and other growths, we have lost sight of the fact that these operations are always done in the median line, while the others are more frequently done in other parts of the abdominal parietes, the former involving no muscular and the minimum amount of other tissue; therefore the two series of operations are not comparable. Furthermore the innocuousness of women to abdominal incision, as compared with men, though generally believed, is yet to be proven, as it is founded upon the fact of their great tolerance of incisions done in the linea alba. It occurs to me that the better practice would be always to make even the exploratory incision in penetrating wounds in the median line.

The Section then adjourned.

A Specific against Cholera and Typhus.—According to a St. Petersburg paper the celebrated Russian traveller Dr. Fodtschenco recently discovered in Turkestan a plant which is said to be an excellent specific against cholera and typhus. It is used by the natives of Central Asia against all kinds of maladies, and every effort has been made to keep its properties from the knowledge of Europeans. The plant, which is named "Ferula Sumbul," has been acclimatized in the Moscow Botanical Garden, and the justly great name of Fodtschenco deserves this notice of its merits.—*Paris Correspondent of Philadelphia Medical Times.*

Correspondence.

OUR LONDON LETTER.

THE BROWN LECTURES FOR 1885—METABOLISM—THE SKILLS AS TO THE NATURE OF CRETINISM—THE BELLS FUNCTION OF THE THYROID GLAND—RESULTS OF REMOVING IT—CHANGES IN THE GLAND IN CASES OF MYXŒDEMA—RECENT NERVOUS PATHOLOGY—NERVE-CENTRES AND THEIR RATE OF DISCHARGE—LOCALIZATION—VIEWS OF MERIC AND SCHIFF—A NEW THEORY OF ANKLE-CLONUS—FUNCTIONAL DISORDERS OF THE CENTRAL NERVOUS SYSTEM PRODUCED BY LOSS OF THE FUNCTION OF THE THYROID GLAND AND PITUITARY BODY RESPECTIVELY—EXPERIMENTAL EPILEPSY.

With the advent of December the season has arrived at which the "Brown Lectures" are delivered. They consist of an annual course of about five lectures, delivered at the London University by the Professor of Pathology at the Brown Institution. This institution was founded in connection with the University of London about ten or twelve years ago, by means of a munificent legacy bequeathed for the purpose by a wealthy gentleman named Brown. It is located in Vauxhall and comprises, in the first place, a hospital for animals, with in-patients and out-patients, and, secondly, a laboratory with appliances for physiological and pathological research. The Professor-Superintendent is expected to make researches, and a condition of his retaining the appointment is that he shall deliver a short course of lectures every year at the University of London on some subject in comparative pathology. These usually embody the results of the researches made during the previous year. Among former professors may be mentioned Dr. Burdon Sanderson, formerly Professor of Physiology in University College, London, and now Professor of the same subject at the University of Oxford. The present holder of the appointment is Mr. Victor Horsley, a former pupil of Professor Sanderson's and a distinguished graduate of the University of London. Mr. Horsley is still quite a young man, but is already favorably known by his investigations. The lectures now in course of delivery are in part a continuation of those given last year, of which some account appeared in your columns at the time.

The first lecture was delivered on December 7th. In this Mr. Horsley proceeded to develop still further the views which he enunciated last year as to the functions of the thyroid gland, the symptoms caused by its removal, and their relation to myxœdema and cretinism. After briefly referring to the terms on which the lectures were instituted and specifying the subjects he proposed to take up in his course this year, Mr. Horsley opened by discussing at some length the subject of metabolism. Metabolic processes, he remarked, must be of two kinds, viz.: constructive and destructive. There must be a controlling influence though this was not necessarily an inhibiting influence. If there were a mechanism of control it must be dual. Excretion was both destructive and constructive. The urinary secretion was an instance of the latter. Excretory functions were much easier to study than the building-up of tissue. The thyroid gland was an excretory body. Such a body did not necessarily possess a duct. He regarded the thyroid as an organ which took up worn-out material and by its functions *led to* the building-up of tissue. He stated last year that myxœdema and cretinism were respectively acute and chronic forms of disease following loss of the thyroid.

He now remarked that there were two views at present current as to the nature of cretinism and cachexia strumipriva. One of these was that it was virtually a condition of chronic asphyxia. This he termed the Swiss view. It was advocated by Kocher and Schiff. The latter had found that in animals from whom the thyroid had been removed and who had reached a moribund condition, life could be prolonged by opening the trachea and performing artificial respiration. But in no case could life be thus prolonged for more than a few hours—twelve at most—and Mr. Horsley remarked that it was known that artificial respiration stimulated the heart and he considered the prolongation of life as due to this cause. The other view, he said, might be termed the English view. It was that the condition was caused by a lesion of the sympathetic.

Last year, he said, he had stated that the function of the thyroid was duplex, viz.: First, that it regulated muciparous metabolism, and, second, it was a hæmapoietic, gland. He now had further proofs of the latter to offer. He had observed that extreme anæmia *immediately* followed removal of the thyroid. Its immediate occurrence showed that it was not due to a secondary cachexia. He had also found (by means of observations made with the hæmacytometer) that the red blood-corpuscles contained in the thyroid vein were markedly in excess of those in the thyroid artery. The relative proportions varied considerably in different cases. This tended to show that the physiological importance of the thyroid varied considerably. These experiments were made on dogs. As corroborative of his view as to the hæmapoietic function of the gland Mr. Horsley referred to its enormous vascular supply.

The loss of function ensuing on removal of the thyroid caused symptoms due to defective nutrition. Mr. Horsley now recognizes three stages in the myxœdematous condition caused by removal of the thyroid; viz., 1, neurotic; 2, mucinoid; 3, atrophic. The third stage, he said, he had only observed since the publication of his previous observations last year. It was marked by general imbecility and atrophy of all the tissues, especially the muscles. It was producible only in monkeys. It had not previously been found possible to prolong life beyond the second stage, but by the application of heat he had been able to do so. By placing the monkeys in a temperature of 90° their lives had been prolonged, but not for more than a month in very young animals. At the onset of nervous symptoms they were placed in a vapor bath at 105° F. The recognition of this stage, he thought, showed a distinction between myxœdema and cretinism. In this case the animal lived through myxœdema into cretinism.

The symptoms due to removal of the thyroid were atrophy, dryness of the skin (lessened by heat), tremors, loss of hair, and caries of the teeth. The age of the animal was an important point. Removal of thyroid produced a greater effect on a young than on an old animal. Mr. Horsley also suggested that the thyroid had an influence on the (real) age of a man, and said he would parody a statement of Dr. Hughlings Jackson, and say that a man's age did not depend upon the number of times he had been round the sun, but upon the state of his thyroid gland. The state of previous nutrition was an obvious factor and stood next to age. The proclivity of females to myxœdema was very marked. The Report of the Clinical Society showed that out of more than one hundred cases only fifteen were males. Mr. Horsley thought that in females special causes might be in operation. In males, he said, the tissues tended more to develop in the direction of specialization. Bone, fibrous tissue, fatty tissue, would be the order in men; the reverse order would represent the tendency in the female sex. The thyroid gland varied with the condition of the uterus. Thus it varied during menstruation and pregnancy. He might remark, too, that in females the mucous tract was somewhat more extensive than in males.

The changes in the thyroid gland from myxœdema resembled those which are senile. There was apparently chronic congestion of the whole gland, and then degenerative changes which were not simple atrophy. Dr.

Hughlings Jackson had suggested that these were due to changes in the medulla.

In the second lecture (December 9th) some account was given of some researches into the pathology of the central nervous system. Mr. Horsley devoted some time to discussing the rate at which nerve-centres discharge. The term centre, he said, was a vague one. It might consist of two cells merely and these cells were not necessarily dissociated from the rest of the nervous substance. Add to these cells two conductors. Stimulation to the centres would differ much in its effects from similar stimulation applied to the conductors. The latter were not capable of originating energy.

Going on to speak of the question of localization of functions Mr. Horsley referred to the divergence between the English views (those of Jackson and Ferrier) and the continental ones (those of Goltz). He thought the differences might be largely explained by the fact that the English experiments had been made on monkeys and the continental ones on dogs. It was pretty well agreed that the fronto-parietal group of cells contained the motor centres. The smaller cells had sensory functions. The paracentral lobule contained enormous ganglion-cells and was the centre for movements of the leg. The cells in the arm-centre were smaller, and those in the centre for the fingers were smaller still. Mr. Horsley suggested that the size of the cells varied in accordance with the part supplied.

Mr. Horsley then referred to the views of Meric and Schiff respectively. Meric concluded from his experiments that afferent impulses go to a sensory receptive area and from thence to the motor cortical centre. Schiff thinks that afferent impulses go straight to the motor area of the cortex which is therefore sensory as well as motor. He found that section of the posterior column of the spinal cord caused paralysis ("ataxia"). This he (Schiff) thought to be sensory, as it disappeared in standing on a rough floor. Mr. Horsley opposed this view. The symptoms also, he remarked, were those of what (in England) is termed cortical paralysis rather than those of ataxy. Schiff's views, he said, were contrary to the ordinary ones, and, if accepted, would cause us to assume a decussation of sensory fibres high up, *e.g.*, in the tegmentum. Mr. Horsley said he explained Schiff's results as due to a blocking of motor tracts. He had repeated Schiff's experiments with antiseptic precautions. These were not used by Schiff.

When the operation was done antiseptically the incision in the cord healed in a few days. Exudation could not then escape but caused pressure. In his own experiments he found that those two in which antiseptics failed and the wound became septic were the two in which he got results most nearly resembling those obtained by Schiff. The results of the others were much less marked. Another explanation he would suggest was that in making the incision in the cord vessels supplying various parts were necessarily divided.

Mr. Horsley then detailed at some length the method he had adopted to determine the rate of discharge from nerve-centres. He found it to be at the rate of from eight to ten discharges per second. This was the same rate as the muscular movements in ankle-clonus. From this Mr. Horsley suggested a new theory of ankle-clonus. It might, he said, be merely a record of the fundamental rate at which nerve-centres discharge. Muscle, being elastic, simply recorded. The stretching of the muscle irritated the spinal cord and thus started the ankle-clonus. Discharges from the cortex, he said, might be at the rate of ten or twelve per second. But in passing through the lower centre (anterior cornu of spinal cord) the latter acted as a transmutor and reduced them to the normal rate. When powerfully irritated the lower centre might become polarized and act simply as a conductor.

The third lecture (December 11th) was opened by discussing the functional nervous disorders of the central nervous system produced by loss of the function of the thyroid gland. The symptoms, remarked the lecturer, followed a degeneration of nerve-centres due to arrested metabolism in the thyroid. They were (1) tremor; (2) paresis; (3) paralysis. The tremor was fine and constant. It was at the rate of from eight to ten per second. After a time it became interrupted and its rate got doubled or trebled. He considered that the tremors were developed in the lowest motor-centres. They might be explained on three different theories, viz., (1) on a theory of perfect automatism, *i.e.*, that the centres automatically discharged themselves at their normal rate of from eight to ten per second; (2) on the theory that, nutrition being depressed, any irritation might cause a centre to discharge itself at its normal rate; (3) on the theory that the defect of nutrition fell first on the inhibitory centres. Mr. Horsley said his own view was that depressed function of the centre caused it to react to stimuli which would have no effect upon it in health. The stimulus, he said, must not be great or the tremors would stop. They ceased on voluntary movement. The next stage was paresis. The extensors were first affected and the fore-paw (hand) was semi-flexed as in (human) paralysis agitans. He used the term paresis, as the paralysis was not complete. The animal moved when offered food. Semi-rigidity (contractures) then came on, but this did not resemble the rigidity following lesions of the cortex, as it only made the movements of the animal slow. Finally paralysis ensued. The attacks were unilateral in character and much resembled hemiplegia in man. After a while, the animals began to improve—especially with warmth—and in a few hours (five or six) the symptoms would pass completely away. As the symptoms were due to depressed nutrition of the nerve-centres, we should not expect epileptic seizures to follow removal of the thyroid, and as a matter of fact they did not. They might occur in the first few days after operation but not afterward. The cortex was "played out."

Mr. Horsley then went on to speak of experimental epilepsy and the effects produced by removal of the pituitary body. The epileptic spasms experimentally produced in animals are, he said, very short in duration, and much less marked than those occurring in man. After removal of the pituitary body, however (which he had successfully effected in two dogs by trephining the base of the skull through the mouth), the cortex apparently became hyper-excitable, and true, well-marked epilepsy could be produced by excitation. Mr. Horsley referred to a work published by Wenzel in 1810, in which the latter stated that in every one of twenty fatal cases of epilepsy, he had found disease of the pituitary body after death.

Mr. Horsley's lectures have not yet appeared in this country, and I have given the above brief account of them from notes taken at the time. The two concluding lectures will be delivered next week. These will scarcely be of equal interest to practitioners with the three already given. Mr. Horsley proposes to take up the subject of canine chorea—a disease, he remarks, which is very common in dogs—and will endeavor to show from the pathological changes found in the spinal cord that it is really disseminated sclerosis.

ARTIFICIAL ALIMENTATION IN CASES OF VOMITING FROM PREGNANCY.

To the Editor of The Medical Record.

SIR: I was much gratified to see in THE RECORD of December 12th, an account of a cure by Brünniche—by the introduction in the œsophageal tube of liquid food, as milk, powdered beef, etc.—of a pregnant woman suffering from uncontrollable vomiting. Except this case, reported this year, I have never known of any case of this sort successfully treated by the œsophageal sound (*gavage*)

but one reported by myself in a series of articles on super-alimentation, artificial alimentation, etc., published in the *New York Medical Journal*, April 19th and 26th, and May 10, 1884. This was a case so desperate that the patient would have died from inanition without the treatment employed, unless, indeed, premature labor had been induced. These cases possess all the more interest, because Dr. Debove, whose experience in artificial alimentation has been very extensive—much greater probably than that of any other physician—and who by his sound has contributed greatly to its practicability, informed me, in the summer of 1884, that he had not found it of use in the inanition of pregnancy resulting from vomiting, although he had, as his published cases show, used it with great success in hysterical anorexia and vomiting.

According to Debove, there is no relation between the appetite of patients and their digestive faculties. The food introduced into the stomach artificially may be tolerated and digested, no matter how sensitive the pharynx may be. The substances employed by me in the case referred to were the powder of beef, the yolk of eggs, and milk.

If carefully studied and employed, I believe alimentation with Debove's stomach-tube will be found efficacious in some cases of vomiting of pregnancy where all other means fail. Respectfully yours,

H. E. Millard, M.D.

4 East Forty-first Street, New York, December 15, 1885.

WHAT IS THE REMEDY FOR THE MEDICAL CHARITY ABUSE?

To the Editor of The Medical Record.

Sir: The command in your editorial of November 28th, to forever hold our peace, if we do not now speak, in case we hold views contrary to those outlined with regard to medical charity and the Charity Organization Society of your city, is heard. This demand to speak, and the fear that the opportunity will forever be gone unless we speak before the declaration, "What God hath joined," etc., I venture to give my views.

Public charity abuse is fast increasing all over the country, and will increase the faster as the public find out there are these places where they can get medical skill, which is said to be the best, for nothing.

The solicitation of funds, Hospital Sundays, etc., advertise the scheme, and only add to the applications. The only reason they are not twice as numerous, is because clinic privileges are not better known.

Many of us in the country, who go down to learn of you, know well how you work, hastening to close your business in the morning to fill your chairs in these places in the afternoon. We envy you the eminence you attain, but are thankful we do not have to work so hard. We try to emulate your policy in founding institutions, but pray to be delivered from your embarrassments. For the consequence we have no one to blame but ourselves when these things come about, and we should be willing to see ourselves as others see us.

What then! The medical profession has assumed the wrong status in its relation to public charities, and in so doing presents an enigma to the public mind which is always a puzzle, and which few can solve and understand. Duty calls the doctor to a share of the charity work, but the rest of mankind observe their vigorous appetites for this peculiar diet with complacency. They cannot and do not claim to do their work for charity's sake. What they suppose to be an elegant system has created an evil at which they are now appalled.

Queries are admissible here. Is it possible that 150,000 or 175,000 persons were *fed* free in New York City last year? (There are a thousand hungry to one needing professional care.) Were there as many persons in all the other walks of life who gave one-third of their time to charitable work without remuneration? Is there as much money spent in clothing, feeding, housing, and warming the needy as is here represented in time and labor at reasonable rates, as is exhibited in charity work by the doctor? All the other necessities of life are met, after a closer investigation as to facts, and the dispenser is held accountable.

So long as the members of the profession stand about the doors of these institutions soliciting a place for themselves, so long charity business will grow. This policy not only exists in the great cities, but all over the country. It founds medical colleges, and the professors receive about the same pay, and the clinics in them are on the same basis, and doctors are made chiefly to organize more clinics. The relation to the sick (the chronically sick especially) is thus made an embarrassing one. Such a relation is not independent or dignified to the physician, for the patient, *if posted*, holds him at a disadvantage. His fees in the country are held to the price of the railroad fare to the nearest clinic, where he knows they will take him in at little or no cost. This is degrading to the business!

The physician outside of these institutions represent to those suggesting to go to free clinics that they are for the pauper, where experiments are made for the benefit of students; they use you for students' practice, they give you half attention, etc., which they find not true when they go there.

Ostensibly these are for the benefit of the poor, the student, the professor, and the growth of the art, and under this policy the competition among the clinics is very great, and it is only the older doctors who venture to question persons who do not seem to belong there. I have known men, "living on their money," to go a great distance and get gratuitous advice from the best of the staff, and I have seen teachers of classes pay patients to allow examinations by students. We go down and sit at the feet of the professors, and go where they have provided the most material and built up the largest clinics, and in this way the growth of the art is promoted and extended; but this is expensive to a proper relation of the sick to the healer.

The Charity Organization in its detective work, by twice the labor that physicians perform in attending the patient, may be able to sift out a few in the cities, but the delay and the expense involved render detection, even in the cities, extremely doubtful; while among those from the country it is almost impossible to make it effectual, especially where it is so easy to hide and go from one clinic to another; taking also into consideration the nature of this detective, the quality of the person necessarily employed to do the hunting, his standing between the claimant of charity and the "rich doctor," and the source from which he must get his pay therefor, and also the difficulty of fixing a scale upon which applicants would be entitled to the aid, makes the work expected of them doubtful of accomplishment.

While the inducement to cross the campus is so great, and severity cannot be used when they attempt it, and the party they wish to see stands beckoning them, the guards will have a hard time of it.

Under the rulings of the Code the only road to fame, the only way to be known, is to belong to an institution with others, with a board of trustees, a yearly catalogue, and an annual commencement, or banquet, with the aspirant's name included in the list.

The remedy? Provision should be made by which we could found hospitals on private enterprise, which now is impossible, except in rare instances. The exigencies demand it (charity hospitals, with paying and non-paying patients together, saying nothing of the many other bad influences, are not the things), and the standard of excellence would continuously be raised by the improvement.

The business requirements should be allowed to take its place upon a commercial basis, and be governed by its laws. It is by unnatural edicts that it is prevented from taking the course that its requirements demand,

and the progress of the times indicate. Specialism has been alike retarded, and is still so, by thus hampering it. The world's history is full of examples of one generation dictating to the next what is right and what is dignity. The floods come and the house does not stand.

It is fast growing that the division of labor is but a forerunner of this other aid to the proper treatment of disease. Such institutions will naturally be in specialties, and they will be centres of large fields of practice, and the query is, in what way can they be made known. Is there no dignified method of doing this?

The undignified part of advertising is bragging, the mention of special qualifications, advantages had, present or former positions, special attainments, relationships, publishing cures, etc. These are all undignified, out of taste, and should be discountenanced; but the simple announcement of one's business, the place of its transaction, when truthfully told, is it beneath the dignity of any lawful business or profession? If thus proscribed, the ethics of advertising would be as well defined as at present, and a clear line of demarcation could be held. The methods of first-class literary institutions are good models. It seems to me that such a policy would but add dignity to the art, for if handsome buildings and costly appurtenances give dignity to the educational profession, why would it not to the medical? When the members of the medical profession confine their hospital work to the institutions built by charity funds, when they sit there to dispense to the most of its inmates for nothing, they are losing the opportunity, to say the least, of a fair exhibit to the world of the value and importance of their work. In our relation to the quack institution at present, we prevent the development of the law of survival of the fittest by chaining ourselves, and allowing the environment wholly to the least fit.

Should we allow this scope to the development of the business and the art, the charity institution would stand where the poor-house now stands, and the irregular would be superseded.

I write this with no invidious spirit. I labor within the pale of the Code and conform to its dictates and rulings, but not without feeling that there is injustice done to the true relation of the profession to the public, by the declaration of principles which, considering the necessities of the advanced methods of treating disease and the modern methods of doing business, are behind the times and retard the development of the art.

Expediencies must supersede manners and customs and old ethics.

Respectfully submitted, E. H. H.

Iowa, December, 1885.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 20, 1885, to December 26, 1885.

Fryer, B. E., Major and Surgeon. Sick leave extended six months on Surgeon's certificate of disability. S. O. 292, A. G. O., December 21, 1885.

Vickery R. S., Major and Surgeon. Relieved from duty in Department of the Columbia, to repair to Washington, D.C., and report in person to Surgeon-General, for duty in connection with Army and Navy Hospital, Hot Springs, Ark. S. O. 293, A. G. O., December 22, 1885.

Reed, W., Captain and Assistant Surgeon. Leave extended one month. S. O. 293, A. G. O., December 22, 1885.

To Disguise the Odor of Iodoform Krieger makes use of the ethereal oil of sassafras. The addition of a few drops, he says, suffices to remove entirely the offensive odor, substituting therefor a fresh and agreeable aroma.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 26, 1885:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
December 26, 1885	5	24	40	3	9	95	4	0
Deaths.								
December 26, 1885	0	[illegible]	12	3	1	43	2	0

A Florida physician the other day conceived the impression that some one was peeping through the keyhole of his office door. He investigated with a syringeful of pepper sauce. In about half an hour afterward he found his wife with her left eye covered with a bandage, so great was the pain of an injury which she had received from a chip which flew up and hit the organ, while she was splitting kindling-wood.

Another faux pas of the Telephone.—"Hello, doctor!" "Hello! Mrs. Elcho." "Clara grows better, and her baby is quite well." At this point the girl at the central office cuts off the doctor and turns on a veterinary surgeon, who is giving the order to his assistant to "Give 'er a bran mash, and have the groom rub 'er down."

Luminous trees are reported to be growing in a valley near Tuscarora, Nev. At certain seasons the foliage gives out sufficient light to enable any one near at hand to read small print, while the luminous general effect may be perceived some miles distant. The phenomenon is attributed to parasites.

A Little Cheeky.—Toward the decline of the cholera epidemic in Sicily, a man named Dr. Riforgiato came to Palermo from Catania, asserting that he had an unfailing remedy for the disease. His assertion found credence among the people, and they carried him in triumph to the town-hall and demanded that he should at once be put in charge of the cholera hospital. When this modest request was refused by the authorities, the people became excited and created such a disturbance that it was found necessary to call out the military to restore order.

Mountain and Sea-air.—Highly nervous persons, the victims of hypochondria, those suffering from excessive brain-work—above all, those in whom these conditions are found in conjunction—should not, as a general rule, be advised to try the sea-side. A quiet inland locality, or some mountainous spot of moderate elevation, will be found to suit their cases better. The monotonous aspect of the sea and the ceaseless beat of its waves are mentally depressing, while the highly strung neurotic patient is irritated instead of braced by the stimulating effects of the sea-air. Those who are just recovering from a serious illness, such as pneumonia or typhoid fever, should not be sent prematurely to the sea-side, as an accession of febrile symptoms is frequently the untoward result. An inland locality is more suitable during early convalescence; but, later on, nothing conduces more to complete cure than a resort to the sea-side. The marvellously restorative effects of sea-air in cases of slight general debility, in persons of strumous habit, and in those with family predisposition to phthisis, are well understood, and must not be regarded as being in any degree impugned by the opinions expressed in the present article.—*British Medical Journal.*

PRESENT STATUS OF THE PNEUMATIC TREATMENT OF RESPIRATORY DISEASES.[1]

BY E. DARWIN HUDSON, JR., M.D.,

THE introduction to the medical profession of the pneumatic cabinet, or pneumatic differentiator, of Mr. Joseph Ketchum has created a renewed interest in the entire question of the value of compressed and rarefied air as therapeutic agents. The fact that Professor Bowditch, of Boston, and the late Professor Armor, of Brooklyn, had consented to stand in an advisory relation, or as sponsors, to those having its construction and use in charge, afforded a guarantee that it was a scientific apparatus, constructed to fulfil the recognized principles of pneumatic treatment. And the detailed and favorable reports of Drs. Williams,[2] V. Y. Bowditch,[3] Boughton,[4] and Jensen [4] have already established the claim of the cabinet and method of employing it to careful consideration and trial.

The subject is one which has occupied the medical mind periodically for nearly a century. As far back as 1800 the Royal Society of Haarlem [5] proposed as a subject for competition "The Influence of Condensed Air on Animal and Vegetable Life." Nothing of value was elicited. Again, Sir John Sinclair, following observations upon lower animals, suggested the application of condensed air to the treatment of human disease. But the great treatise of Laennec, in 1819, makes no mention of pneumatic treatment. In 1835 M. Junod [6] made the first authentic experiments as to the influence of compressed air on the human body. Majendie and his colleagues reported adversely upon M. Junod's conclusions, but at a subsequent period the French Academy, with full appreciation, reversed its verdict, and awarded M. Junod a medal of honor. Attention became fixed as to the significance of pneumatic therapeutics. Efforts were made, as expressed by Ramadge,[7] at "establishing the normal relation between inspiration and expiration." Ramadge's tubes are pictured and described in his translation of Laennec. Definite treatment by immersion of patients in reservoirs of compressed or rarefied air was conducted from 1850 to 1857 by Tabarié,[8] Bertin,[9] of Montpellier, Pravaz [10] and Millet,[10] of Lyons, and A. Simpson.[11]

Tabarié's spheres were of iron, and would hold from one to twelve persons. He advised sittings of two hours duration, with an increased pressure of from one-half to two-thirds of an atmosphere. A course of thirty to forty sittings was advised for radical cure.

Bertin pursued similar methods, employing, as did Pravaz and others, the spheres of Tabarié. He reported the cure of fifteen cases of uncomplicated emphysema, and of ninety-two cases of nervous and catarrhal asthma, with associated emphysema. Sixty-seven are reported as cured, twenty-two as benefited, and three as unsuccessful. Air-chambers, cumbrous, expensive, and not portable, were thus far used.

I. Hauke,[1] of Vienna, is said to have first devised available portable apparatus for therapeutic uses, and to have led Waldenburg to give his attention to the subject.

Waldenburg devised the apparatus now bearing his name, and accumulated physical data and clinical observations enabling him to formulate a system of pneumatic therapeutics.[2] He devised a simple and portable apparatus for condensing and rarefying air, without delay, for consecutive or alternating use at the same sitting. It has been well compared, by Dr. J. H. Emerson,[3] as to appearance and principle, to the storage vats for illuminating gas. One cylinder, with an open end downward immersed in water, within a second and larger clyinder. By means of lateral uprights, with cords, pulleys, and graduated weights, the upper cylinder may at will be lowered and raised, and its contained air either condensed or rarefied. Tubing and a mouth-piece complete the apparatus.

In determining the indications for pneumatic treatment in different thoracic diseases, Waldenburg was largely guided by the causes of dyspnœa, whether the product of inspiratory or expiratory obstruction, or both. He concluded that in emphysema retarded expiration is alone the cause of dyspnœa; that in stenosis of the upper air-passages, and in most forms of bronchial catarrh, including submucous thickenings and bronchial distortions, inspiration alone is interfered with. In phthisis he regarded inspiration as chiefly obstructed; expiration also, but to a lesser degree.

For the above conditions he employed and rarefied air in accordance with his conception of the chest dynamics as related to the pneumatic forces at his command.

His methods may be briefly summarized as follows: 1, The inspiration of condensed air; 2, the expiration into condensed air; 3, the inspiration of rarefied air; 4, the expiration into rarefied air. The second method, expiration into condensed air, was found impractical; the third, inspiration of rarefied air, was found of doubtful value and often attended with danger. The first and fourth methods, viz., inspiration of condensed air, and expiration into rarefied air, alone were announced to be of value. The inhalation of condensed air was regarded as the method indicated in all cases of stenosis of the upper air-passages, in contraction of air-passages, obstruction, occlusion, or collapse of terminal tubes and air-sacs; the expiration into rarefied air was demonstrated the correct method indicated for the treatment and radical cure of emphysema.

Concerning the latter method, the subsequent testimony of very many observers is cumulative and enthusiastic. The testimony as to benefit from pneumatic treatment in chronic bronchial catarrh, caseous phthisis, chronic interstitial pneumonia, contracted chests from pleuritic adhesions and pleuritic thickening, is less unanimous.

The introduction of a cabinet like that of Ketchum and Williams, which enables the patient to combine inhalations of atmospheric air, heated air, and medicated at the barometric pressure of air as ordinarily inhaled, with diminution of atmospheric pressure on the thoracic walls and peripheral circulation of the entire body, will help to solve the many unsettled problems of pneumo-therapy. This cabinet is, then, the most complete yet offered to scientists and the medical profession for testing the clearly-formulated principles of pneumatic-therapeutics given to us by Waldenburg. Dr. Mitchell Bruce[1] has well said: "Air stands in a dual relation to the economy as a definite compound of certain gases, and as an atmosphere with a certain pressure." The apparatus of Waldenburg, approaching the mouth only in inspiration or expiration with a column of condensed or rarefied air, did two things: 1, Afforded either an increased or diminished supply of oxygen; 2, produced increased or diminished pressure on the interior of the air-passages and pulmonary vesiculi.

The cabinet of Ketchum and Williams does all this, and further, removes pressure from the peripheral circulation of the entire body, inducing determination of blood away from internal viscera to the surface, drawing the chest-wall outward, increasing its capacity. This being done at the same time that the inspiration of atmospheric air (relatively condensed air) dilates the bronchi and vesicles, and compresses their vascular channels, the promise of increased chest capacity, and reopening of contracted tubes and collapsed alveoli is very great. How far this is desirable, safe, and curative, only cumulative testimony can determine. To this purpose the wisest precautions have been taken by the projectors of the cabinet and its method of use as to the disposition of the cabinet, entrusting it only to safe hands, and for use in suitable cases after a discriminating diagnosis. The cabinet of Ketchum and its method of use have been thus described by Houghton:[2] "The cabinet is an air-tight chamber, in which the patient sits or reclines, breathing from the outside through a flexible tube. We exhaust a small portion of the air about him, causing a deep, easy, and pleasant inhalation, filling every part of the lungs with the air or spray, producing a stronger and more regular circulation, bringing the blood into complete relation with the oxygen of the air, and introducing the medication in every recess with ease. We have now simply aided the patient to take a deeper breath than he otherwise could. We can then either produce a compression of air about the body, compelling an evacuation of the lungs, and repeat the former movement, or we can continue the rarefied condition and let the patient expel the air by his own effort. In this latter way we produce the same effect upon the lungs that a dumb-bell does upon the muscles of the arm, for the effect is to exhale and not to inhale. We thus have such complete control over the movements of respiration that we can increase or diminish the force, frequency, and depth of each breath at our pleasure, and without the slightest effort or discomfort on the part of the patient." It should be clearly understood that the departure in atmospheric pressure for therapeutic purposes, both for condensed and rarefied air, is quite within the limits of safety, even for the most delicate structures of diseased organs.

It must be remembered that Waldenburg's methods propose but an increase of from $\frac{1}{60}$ to $\frac{1}{40}$ of an atmosphere for condensed air, and diminution of a fraction of an atmosphere for rarefied air. The Ketchum cabinet proposes only a fall of $\frac{1}{10}$ to 1 inch of barometrical pressure, or a minimum rarefaction of $\frac{1}{30}$ and a maximum of $\frac{1}{20}$ of an atmosphere. The observations of Dr. A. H. Smith in the study of the Caisson Disease[3] demonstrated that, with an increase as great as fifteen to twenty pounds to the inch, no bad symptoms followed, either from the long immersion in the condensed air of the caisson, or from the sudden transitions to and from the external air. Not until a pressure of forty or fifty pounds more superadded were the brain and cord engorged, or the possible introductions of nitrogen into the blood effected.

Vivenot employed as high as $\frac{3}{4}$ of an atmosphere. Flint[1] mentions beneficial treatment by one, and even as high as five atmospheres. Bartholow favors a chamber with 1½ or 2 atmospheres. The phenomena following an initial inhalation of condensed air, as stated by Bruce, are "pallor of skin and mucous membranes, sensation of pain in ears, diminished frequency of respiration, but the act becomes easier; enlargement of lungs, increase of vital capacity, as shown by the spirometer; depression of the cardiac force, and diminution in size and force of pulse, and rise of temperature." Frequent exposures to condensed air increase the bodily strength. These results are attained: first, by increased supply of oxygen; second, by increased pressure.

As to the beneficial influence on the heart, Niemeyer may be cited. He says that inhalation of compressed air is "the most efficacious of all dietetic remedies, in the widest sense of the word."[2] The pulse, under the influence of compressed air, is reduced from 12 to 15 in the minute. Rosenthal[3] compares compressed air to digitalis in small doses, in its effect on the heart, and advises its use in mitral and aortic lesions. Not only does compressed air strengthen the circulation, but it equalizes the two circulations, increasing tension within the left ventricle, lessening tension in the right. Pressure is transferred from the venous to the arterial channels. Oxygen gives better blood, digestion is improved, and strength is the result.

Compressed air can be administered with uniformity of pressure, and for sittings of sufficient duration to be valuable, only by use of a cabinet. The compressed-air cabinets formerly constructed had necessitated the application of the same pressure on the exterior of the body, and on the interior of the air-passages.

The new cabinet reverses this order, by subjecting the periphery of the body to rarefied air, but admitting atmospheric air by a tube to the mouth and air-passages—a relatively dense air. It therefore fulfils all the requirements for the pneumatic treatment of phthisis, of local and diffused infiltrations, collapse of vesicles, constrictions, and catarrhal tumefactions of bronchial mucous membranes.

It has been suggested that the Ketchum cabinet is not adapted for the treatment of emphysema. The latter disease, it has been thought, demands: first, inspiration of positively condensed air, *i.e.*, a requisite amount of oxygen to aerate the blood within a lessened volume of inspired air; and second, expiration into a column or volume of rarefied air, producing a suction, or "pneumatic aspiration,"[4] of the residual air, and thus progressive collapse of dilated emphysematous vesicles and spaces.

Trial of the cabinet already has demonstrated its usefulness in many cases of emphysema. Its gymnastic exercise of pulmonary elastic tissue, as described by Houghton, would warrant the expectation of its usefulness in this disease. One of the questions which this most valuable apparatus may help to solve is the superiority of pneumatic artificial methods above simple methodical chest expansion. In the treatment of poorly-developed, weak chests, of pleuritic thickenings and adhesions, of bronchial warping and contraction, of chronic bronchial catarrh, and of the various stages and forms of early and late phthisis, systematic efforts at voluntary chest expansion are most efficacious. The ordinary increase of chest measurement in quiet breathing is but a half-inch to an inch. Yet by forced effort an increase of two or three inches can at once be secured. So, too, in normal quiet respirations twenty-six cubic inches of air are inspired, yet double, treble, nay, six or seven times that amount, may be drawn into the chest by

[1] Practice of Medicine, p. [illegible], Ed. 1881. [2] P. 89, "Vol." Ed. N. Y., 1874.
[3] Zeitschrift, vol. [illegible], p. [illegible]. [4] Chew Pebber, vol. [illegible], Emphysema.

forced breathing. Tubes are distended, air-sacs ordinarily inactive or feebly expanded are brought into fullest action, increased oxygenation is produced, blood is more fully vivified, and heart and circulation stimulated; strength results, and a general improvement of nutrition. Even with pronounced serum of the pleura, bronchi, or pulmonary parenchyma, this result can be attained. The phthisical chest, by means of systematic chest expansion, especially after the method formulated and so long used by Leaming,[1] results, after a very brief time, in a progressive increase of circumference of chest, of two to three inches and more, and often a re-development of both normal vital capacity and full respiratory motion, with consequent health. If, added to such methodical expansion, treatment by inhalation of condensed air or medicated vapors be employed, in spray, as the balsams or other astringents are employed, still further curative results have followed. The mechanism of this natural method is in accord with the principles and purposes of the artificial method—the employment of cabinets and condensers. That the cabinet of Mr. Ketchum may prove even more efficacious where it can be made available, I am willing to believe.

Many other therapeutic problems may be solved by the Ketchum cabinet. The withdrawal of peripheral pressure favors elimination by the skin; it also relieves venous engorgement and vascular tension in the kidneys and liver, and permits the depurative functions of those organs to be resumed—functions so often vitiated by interstitial deposit, induced by the obstructive changes in circulation within heart and lungs, or, in common with them, the product of a rheumatic or gouty bile.

THE PHYSICS OF PNEUMATIC DIFFERENTIATION.[2]

By JOSEPH KETCHUM,

BROOKLYN, N. Y.

In the spring of 1883 the author was invited by Dr. Herbert F. Williams, of Brooklyn, N. Y., to investigate the existing devices and methods for inhalation. He remarked, "If only some sure method of topical application to diseased lungs could be made, it would be a great stride in the treatment of pulmonary disease." By a thorough investigation of known methods, and an analysis of their defects, I arrived at the following conclusions: The range of theory *must* be in the field of Pneumohydrodynamics. The vehicle must be air—the only medium tolerated by the lungs. Physical forces must be employed to control and bring into relation physiological law and anatomical conditions. The agent must not only be conveyed to, but surely deposited in, the desired locality.

A study of the anatomy of the organs of respiration and their muscular environment, together with the physiology of respiration observed from a philosophical standpoint, presented the following inevitable considerations.

The obstacles presented were: First, relatively high temperature of the lungs compared with that of inspired air. Second, resistance due to bronchial friction. Third, remoteness of the regions usually affected from the larger bronchi. Fourth, the normal limitation of respiratory energy to merely partial collapse of the lungs, and the usual impairment of that energy in disease.

In considering any method of overcoming, and perhaps utilizing, these recognized conditions, the following limits present themselves:

1. The burden of moisture or vapor with which air may be charged.
2. The tensile strength of diseased pulmonary tissue.
3. The interference with other physiological phenomena.
4. The latent muscular strength of the subject.

[1] Leaming: [illegible]

[2] Read before the Section in Practice of Medicine of the New York Academy of Medicine, December 15, 1885.

Now, what is the value of the obstacles noted?

First, as to relative temperature, with the barometer at 30 inches. Air inspired at 70° F. has a tension of .733 while at 90° F., which is approximately the temperature at expiration, its tension has been increased to 1.410; this difference in the tension of the aqueous vapor indicates the increase in its hygrometric capacity; or, in other words, its capacity for water has been increased in the above proportion; consequently a constant process of evaporation from the aerating surface is going on, which, according to the researches of Valentin (Dalton, p. 235), is 8,100 grains, or about 1¼ pound avoirdupois daily. It is therefore clear that, with any method applied under natural conditions, respiratory air charged with moisture at a temperature below that of the lungs, not only retains its moisture during the complete act, but acquires an additional quantity by evaporation from the pulmonary surface, in exact proportion as the pulmonary temperature is imparted to the inspired air.

By what artificial aid can this process of evaporation be not only checked, but the natural process be reversed, and the air be compelled to deposit instead of acquire moisture when within the lungs?

The two conditions hostile to the deposit of moisture are the contrasted temperatures, and their variations of aqueous tension.

The former is beyond control; for no artifice can safely invade the lungs to sufficiently reduce their temperature. We can, however, compel condensation, by inter-pulmonary compression, to an extent that will not only counteract the increase of tension, but will leave a margin sufficient to effect this condensation. If a lung is surrounded by an atmosphere equal to a barometric height of twenty-nine inches, while its interior is exposed to one of thirty inches, a differential pressure equal to one-thirtieth of an atmosphere is exerted against the walls; and to effect expiration this pressure must not only be overcome, but muscular or other force must be exerted sufficiently to overcome its inertia, as well as the capillary and bronchial friction heretofore referred to as the second obstacle.

Manometric tests show that in respiration, under the circumstances stated, the expiratory effort is equal to a difference of 4.5 inches of the manometer, and that a pressure five and a half times as great as that at which air enters, is necessary to dislodge it. This increase in pressure reduces the carrying capacity, or hygrometric condition, and is equivalent to a reduction of temperature, and a resulting condensation of the vapor from the air respired.

Second. The usual remoteness of lesions from the larger bronchi.

The usual remoteness of lesions from the larger bronchi is observed, and the connection between the cause and effect springs into prominence. Having demonstrated that wherever saturated air penetrates, its physical properties can be so changed that condensation ensues it only remains to prove that these localities are penetrated by saturated air, and the topical application is demonstrated. Spirometric tests show that, while tranquil inspiration amounts to from fourteen to eighteen cubic inches, the initial inspiration, aided by the differentiation of the breathing and the surrounding atmospheres, amounts to from twenty-eight to forty cubic inches, dependent upon the differentiation; and this excess over tranquil respiration must penetrate to regions only partly used, or entirely disused, in ordinary respiration. Boyle's law (that gases at a given temperature occupy space inversely to their pressure) will not account for this difference of forty or fifty per cent., even though we had no other means of verification; but auscultation, under these differential circumstances, in the regions above noted, shows that air is entering and circulating with a freedom that demonstrates the penetration to these regions of the increased volume of air.

Third. The limitation of respiratory energy with its

impairment by disease, is overcome by supplying the force denied, for without sufficient expiratory force condensation cannot be effected; but expiration is effected to a greater or less extent, depending on the subject, or the differential force employed, and to exactly that extent is condensation produced.

Having presented the obstacles, and the means by which they may be removed or used as favorable factors, let us determine the limits within which they may be applied.

First. Of prime importance is the limit of humidity with which we can burden our only means of transportation to lobule and vesicle; and this limit is reached when the respiratory column of air is charged with not only all the moisture that the surrounding barometric and thermometric conditions will permit, but also all that can be imposed on it in a state of high mechanical subdivision.

Second. Next in importance is the limit of tensile strength of diseased pulmonary tissue; and here is met the same responsibility which is assumed by the physician or surgeon in every operative procedure, or the employment of any muscular force. The same judgment which gauges the force of forceps traction or estimates the proper amplitude of forcible flexion of an anchylosed joint, must guide him in the application of this force to the lung tissue. The method is exceptionally secure, however, in that the force at command is subject to voluntary graduations, ranging from the delicate influence which determines the depth of the fish in its element, to the enormous energy which in a surface-blast of dynamite rends the rock before the atmospheric inertia is overcome.

We are free from the errors of judgment sometimes accompanying operative procedure, where muscular effort may be miscalculated.

The pneumatic force is indicated by gauges which are a constant reminder of the force employed.

Third. Interference with physiological phenomena. Here we meet the first question in which philosophical theory does not furnish exact data, and knowing that any interference with the equilibrium of the respired atmosphere must exert a direct influence on the circulation, and through it on its source of energy, the heart, we are driven to the domain of experiment to determine how far we may safely resort to such interference. Exhaustive investigation made by Drs. Tiegel and De Watteville, of New York, and reported by the former in an article published in the *Journal of the American Medical Association* of November 28, 1885, definitely shows how far this interference can be carried, and under what conditions it is indicated or contra-indicated.

Fourth. The normal limitation of respiratory energy requires only a moment's consideration, for while the amount of condensation produced by the patient's effort is limited by his expiratory power, the slightest thought shows that the same power that filled and dilated his lungs may be brought to bear in collapsing them, by the reversal of the process, and by mechanical means succeed when nature impaired by disease fails. To deny this is to question both the efficacy and appropriateness of the Marshall Hall or Sylvester method of artificial respiration.

I have endeavored to confine the range of invention to its narrowest possible limits, and to make the product fit the necessity. The details of the method and its requirements naturally follow. In order to utilize "air in its greatest vapor-carrying capacity," the influence which renders its weight appreciable must be employed, and the rarefaction of the surrounding atmosphere becomes the essential part of the process. Muscular contraction will in most cases give the physical condition necessary to condensation, but the process should be armed against the emergency of a failure in this respect; and this renders it imperative that there be incorporated a method of mechanical compression of the surcharged air, which must be sufficient to supply the deficiency of expiratory force on the part of the subject, as well as to overcome the friction and inertia of inspired air.

The instrument constructed to comply with the above requirements is a cabinet of proper size and shape to hold a man in the sitting posture, and rigid enough to withstand the superficial pressure when rarefaction is produced inside; strong enough to stand the jars and jolts of transportation, yet light enough to be taken from office to office, or from doctor to patient. It is made of steel sides, bottom and top fitted to a wrought iron angle frame, with a heavy glass front and a door in the rear, air-tight when closed, but capable of being opened at an instant's notice. In front and below the glass is a projection which sustains the atomizing apparatus and medicine receptacle. In the centre of the glass an aperture is pierced through which the breathing-faucet penetrates far enough into the cabinet to allow a soft rubber breathing-tube to be slipped on. The breathing-faucet is constructed of hard rubber, and is of such shape and design that when in use the condensate collecting in it on the patient's side of the stop-cock flows out through a drip-hole in the latter, while the condensate formed in front flows back into the medicine receptacle and is re-used. At the side of the projection is another stop-cock entering the steel front of the cabinet, used for decreasing the rarity or pressure inside the cabinet without removal of the breathing-tube from the mouth of the patient. In front and immediately over the glass is a manometer gauge connecting with the interior of the cabinet, filled with mercury to the zero point and graduated to $\frac{1}{10}$ inches. On the top or roof is a bellows whose interior capacity is approximately one-thirtieth of the cubic capacity of the cabinet. The interior of the bellows, by a valve in its floor, communicates with the interior of the cabinet. This valve is operated from the inside of the cabinet. The bellows communicates with the outside air by another valve in its upper side operated from the rear of the cabinet. The bellows is operated by a rock-shaft running across the top of the instrument, supported by shaft standards on each side, and to one end of which an operating lever is keyed. The saturation of the air is accomplished by the use of an atomizer and stand operated by compressed air or steam, and of such height as to deliver its spray directly into the mouth of the breathing-faucet.

The method of administration is so simple that, under the general instruction of the physician as to medication, length of time, and amplitude of force as indicated by the gauge, it can and has been satisfactorily used by the invalid's ordinary attendant.

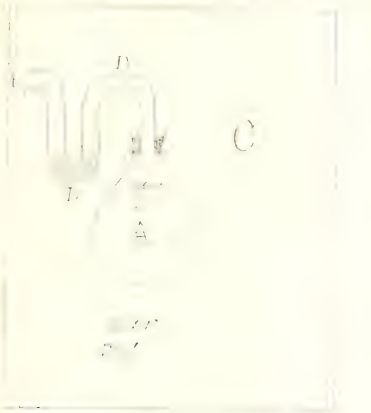
The patient is first instructed in the method of respiring entirely through the mouth, and is told that while the air will flow down into the lungs without any effort, a slight blowing force will be necessary to expel it preparatory to the next inspiration.

He is next told that when the air of the cabinet is rarefied he may experience a slight swelling of the tympani, and to relieve which he is instructed to swallow, thus opening the meatus of the Eustachian canal, and allowing sufficient of the air enclosed to flow into the throat to produce equilibrium with the surrounding atmosphere. He is next seated in the cabinet on a chair adjustable for height, and raised or lowered until his mouth is on a plane of slightly higher elevation than the opening in the glass front, and a clamp is placed on the external nares to prevent the escape of air by that channel. The door is now closed, the valve-rods having previously been placed to indicate that the valves are set to produce rarefaction; the operator passes to the front of the instrument and, having closed the breathing and auxiliary faucet, with his eye on the gauge, moves the lever operating the bellows toward the rear with a slow, even motion, until the difference between the levels in the two arms of the manometer indicates a rarefaction of, say, from one and a half to two inches.

The object of this procedure, before beginning the treatment proper, is to expand the residual air in the lungs, and if any has been imprisoned behind mucus, or catarrhal plugs, or infarctions, to exert a pushing influence from behind and toward larger bronchi, and produce

ultimate evacuation. This is demonstrated by the following experiment:

The gas-flask A is fitted with the bent, [illegible] tube D, in the curve of which a small quantity of colored glycerine, or other fluid, is introduced; this remains at the bottom of the curve B only so long as the [illegible]



on the flask side is equal to that on the open side, E. Now, if the atmospheric conditions are so changed that the atmosphere in C is rarefied to the extent of, say, one inch of the manometer, then a pressure is exerted on the fluid B by the air in the flask A, in its effort to restore equilibrium, which will drive it out of the mouth of the tube at E. Supposing the flask A represent the air occluded, B the infarction, and D the connecting bronchus, trachea and mouth, and the application is evident.

The rarefaction is now allowed to run down by the use of the auxiliary faucet until the manometer indicates the amount deemed proper by the attending physician, and the spray having been adjusted to the breathing-faucet and turned on, the patient is instructed to take the breathing-tube and place the mouth-piece with which the end is fitted in his mouth, in front of and against his teeth, enclosing the rim with his lips to prevent displacement by the interior pressure. The stop-cock is slowly turned on. Nature asserts herself, and the inflation of the cheeks and rise of the thoracic envelope indicate that the restraint first offered by the stop-cock is now offered by the cell-walls, and the same influence that is distending the cheeks so markedly is distending the alveolar walls.

This first inspiration has distended every cell and avenue, and the process of diffusion with the air charged with vapor of the medicament proceeds with a rapidity commensurate with its enlarged avenue of approach, and the act of expiration commences. This is brought about by the patient's forced muscular expiratory effort, and the pressure of the cell-walls on the loaded air reduces its hygrometric condition to a point where condensation is effected exactly in proportion to the energy of the effort, minus the effect of the increased temperature. Subsequent respiration is no greater in amplitude than normal, except in so far as the feeling of inflation may induce a greater expiratory effort; but after a time the patient becomes fatigued, notwithstanding frequent rests (during which he respires the air in the cabinet), and the expiratory act becomes labored. The door is now opened and the valves, inside and out, are set for vibration of the enclosed atmosphere synchronously with the respiratory act from plus to minus, the weight of the outside air. In other words, the top valve is closed and the bottom one opened wide. The door is again closed and the breathing-faucet is opened, and with the lever the bellows is raised until it has reached an elevation equal to one-half its height, and the patient is instructed to again place the tube in his mouth and make his first act one of inspiration. At the same time the operator raises the bellows to its full height and holds it during the interval preceding the expiration. Then, allowing it to descend to the midway point, he forces it to complete collapse, thus compressing the air to the extent of one-half the contents of the bellows, and by this compression forcing the collapse of the thoracic walls and consequent compression and condensation. This method continues, if used as a pulmonary calisthenic, or as a "means of topical application of remedial agents," until in the judgment of the operator the dose or exercise is deemed sufficient. The influence of compressed air surrounding the patient while he is breathing at normal density, of course exerts its influence in a contrary direction, except in relation to condensation, where the outflow of air is retarded by the constricted condition of the glottis during expiration (Dalton, p. 233). This anatomical verification of the conclusion arrived at, independently, by logical deductions from the action of the manometer in estimating the dynamic value of expiratory energy, is as welcome as it is conclusive.

The question of the diffusion of gases relates to the subjects at hand only so far as it applies to the interchange of the same gas under different physical conditions, viz: their relative humidities. In a normal tranquil respiration the amount of diffusion of wet residual air into comparatively dry tidal air, and in a given time, depends upon the size of the avenue through which such diffusion must take place; the relationship in volumes between the tidal and residual air being as 1 to 10, or 20 to 200 cubic inches (Carpenter, p. 300, ed. 1885).

Now, if the volume of tidal air be increased to 40 cubic inches by aid of differentiation, a corresponding dilatation of the cell structure is effected and the avenue through which the diffusion takes place is correspondingly enlarged. The relationship of volumes has now been changed and is 1 to 5, or 40 to 200 cubic inches, and a greater amount of diffusion in the interval between inspiration and expiration is accomplished.

Under the last-named circumstances the physical conditions have been reversed, and instead of 200 cubic inches of residual air diffusing its moisture into 20 cubic inches of comparatively dry tidal air, we have 40 cubic inches of tidal air diffusing into the residual air the moisture with which it has been burdened.

The increase in osmosis of O and CO is apparent, but must be investigated by the physiologist rather than the physicist.

The use of differentiation of the respiring and surrounding atmosphere has been likened in effect to the use of compressed air of the same relative density. In the condensed air method, of which the Waldenburg apparatus is perhaps the best example, the forcible expansion of inter-pulmonary tissue is effected by the exhibition of pressure from without, aimed at it from in front, and maintained during the entire act, or only during inspiration, and is exerted in direct and limited lines of force. This energy tends in no way to assist inspiration, but is simply forced into the air avenues whose remote end is closed, and whose enclosing space is already occupied by the residual air. The pressure is also equal in all parts of the lung, the thin septa of cell-walls bearing the same strain as the comparatively strong walls of the bronchi. The use of air under pressure of course reduces its ability to carry moisture, and denies us the use of the agency of pressure to effect condensation. The method employed in the differential scheme as applied, the use to which the compressed air apparatus is limited, is exactly the reverse.

In the pneumatic cabinet the dilatation is produced by the physical enlargement of the thorax and abdominal area, the recession of the diaphragm into the abdominal region, and the proportionate enlargement of each cell toward the occupancy of the enlarged thoracic cavity. Each cell and avenue, in obedience to physical law, is

now inviting new air to enter with an energy limited to its structural environment, and controlled by the tensile strength of its individual wall. One can hardly confound the force radiating from each point of superficial surface away from the centre, to that which radiates from the centre toward each point of interior surface, and which must always be limited to the tensile strength of the weakest cell-wall.

By the compressed air method the tidal air is forced first into the larger bronchi, where meeting the residual air, its force is first felt and the bronchi are correspondingly enlarged, when they in their turn aid the pressure in condensing that in the bronchioles and alveoli; but long before this point is reached and the pulmonary atmosphere is equalized, the capacity of the thorax in its position at expiration is occupied, and the energy of the compressed air is devoted to the elevation of the thoracic envelope and the depression of its floor. During the process of equalization the forced expiration takes place, combatting the pressure of the gasometer and losing the benefit of a proportion of the elasticity of the normal air by its condensation, and limited by its rigid surroundings. By the time expiration is finished equalization has taken place, and the volume of air under pressure is circumscribed on one side by the iron walls of the gasometer, opposed on the other by the thin septa of inter-cellular tissue. In the differential method the rarefaction of the surrounding air places the thorax in the position of forced inspiration. Each alveolus, bronchiole, and bronchus is expanded to a degree dependent upon the structural strength of the part. The residual air is expanded, and each atom separated from its neighbor invites a new-comer from the tidal air to occupy the space made vacant by their separation.

Expiration commences, and now, without the removal of the initial pressure, the strain on the inter-pulmonary walls is modified by the enormous elasticity of the respiring atmosphere, confined only by space itself.

The personal equation of the subject is important, for while one will involuntarily close the throat against a stream of air projected *at it*, however gently it may be done, and an effort of will is required to effect inspiration, the *aspiratory* influence which *invites* the stream of air of the same force will be accepted without a sign of antagonism.

The cabinet is the merely mechanical expression of a theory. Its scope and applicability can only be known and utilized through investigation and experience. Already it has stimulated physicians to the deeper investigation of pulmonary therapeutic agents. The use of chemically dry air in imitation and elaboration of high altitude and climate, of the introduction of germicidal or nutritive agents to the absorbing surfaces of the lungs, and its possibilities as an agent of resuscitation from traumatic or other coma, are being pushed with evidence of ultimate success.

I have endeavored to avoid the quotation of physical laws as enunciated by such authorities as Gay-Lussac, Regnault, Boyle, Torrecelli, and others, choosing the logical rather than the mathematical method of elucidating the physical aspect of the process.

It would be unjust indeed were I to close without acknowledging my deep obligation to Dr. Herbert F. Williams, my friend, and in all that pertains to the science of anatomy and physiology, my preceptor.

The recent death of Professor Samuel G. Armor deprives me of the opportunity of personally paying to him the tribute due for his active interest, valuable advice, and unwavering support during a year of anxious study and experiment.

THE ÆSTHETIC APPLICATION OF DENTAL ART.[1]

By W. AUSTIN CURRIE, D.D.S.,

INSTRUCTOR IN OPERATIVE AND PLASTIC MANIPULATIONS, BOSTON DENTAL COLLEGE.

On different occasions during my period of practice, I have been requested by patients to explain why it is that dentists seem to know so little about art. What can I say more than to confess that I do not know? I have found repeatedly that such a reply does not in any sense afford satisfaction to the inquirer, or tend to extricate me from an embarrassing position, but only serves to push me more deeply into difficulties.

The query in the outset was prompted, probably, by a passing thought, and had they received any convincing reply, their momentary inquisitiveness would have been gratified and the subject dropped then and there.

But, perceiving my inability to give any reason why a profession so entirely made up of artistic requirements, should have no facilities for cultivating an æsthetic taste in the dental colleges, their curiosity naturally became aroused, and I regretted that I allowed them to see that the question was too much for me.

And can we wonder greatly that such questions meet us, when we reflect that one of the two greater branches of dentistry consists entirely in restoring nature by art?

What is Art? Of all the short words in our language there are but few which are handled more frequently, and that, too, by persons who really have but a faint idea of what those three letters signify. How many of the thousands of sight-seers who visit the galleries of our own and foreign countries, and are thus permitted to look upon the work of celebrated artists, comprehend that the creations before them are the result of the careful study of a lifetime. They are only conscious of the general effect of a work of art, and do not realize what a vast amount of study and labor is required to attain such grand results.

For the sake of illustration, let us for an instant glance at a painting. The artist has presented his work true to life; almost too much so to be pleasant. It has been truly said, that, next to the actual pain experienced in being a party to sorrow is the touching suggestion which a faithful picture communicates.

Wandering over the canvas, our eye first notes the general interest; we remark the excellency of the drawing, the perspective, and the coloring, but soon our attention becomes riveted on the central object, a representation of an old woman, a glance at whose face at once proclaims the *special* motive of the work. The scene is a court of justice, with all of its characteristic stiffness and its unpleasant suggestiveness. Spectators are there with faces full of feeling. The learned lawyers, in powdered wigs, are there true to life, while, in contrast, stands this poorly-dressed woman before the judge who is about to pass sentence of death upon an only son. She is offering a mute appeal—no words of supplication; but the trembling arms and old withered hands outstretched, tears flowing over wrinkled cheeks, the intense agony so plainly depicted on every feature, is an appeal more touching than any eloquence the tongue could have offered. Such a picture commands the attention of every beholder; but how few realize what an immense amount of work it required to reach such a mark of perfection! What an insight into human nature was called for to enable the artist to portray this touching scene! Do they reflect upon the fact that a knowledge of anatomy, physiology, and other studies are required, as well as of colors and their application? Many persons have a faculty of painting a fair representation of the human face upon canvas—they are said to be talented in that respect. But if they expect to approach anywhere in the vicinity of perfection they must be acquainted with the forms of the bones of the head, as well as the muscles and softer tissues. How

[1] Read before the Alumni Association of the Boston Dental College, Boston, October [illegible], 1885.

can they truthfully give the form of the outside without some knowledge of the framework within?

Now, if this knowledge is indispensable to an artist, why should it not be equally desirable that the mechanical dentist should be conversant with its principles also?

An artist, by making himself intimately acquainted with the human form, and by his perceptiveness, power of imitation, and deftness of hand, can place a representation of it upon canvas. He can counterfeit any feature and bring forward any expression. If his work be sculpture, he does away with deception by placing actual shape before us. The one deceives the eye by light and shade, the other gives us substance, the natural light contributing the appearance by which we distinguish the different forms of objects. With the dentist, the object is the same; but, unlike the former, he has not blank canvas or hard stone to work upon, but has living tissue, on which he can learn to put different expressions. Many will say that expression comes from the mind, and that we have no control over it except in our own features. True, it comes from the mind, but it shows itself upon the face, and different expressions are but the result of the action of different muscles in moving portions of the skin (and underlying tissues) so that a new light strikes upon it; this varying light, with its consequent shade, adds a new aspect to the countenance.

An artist can change the whole expression of a painted face by the addition of a little extra light and shade, and that with but a few strokes of the brush. All he does is to *apparently* raise some portions with light and cause others to recede by rendering them a little darker. If colors will change the countenance by appearing to raise portions, is it not patent that *actually* raising those parts will do it even better. It takes but the slightest change in position of the lips and adjacent parts to make a great change in expression. You will put greater faith in this assertion if you will experiment a little yourselves.

Take a portrait, or better, two, precisely alike. The lithographs such as are exhibited in the street-windows by theatres will answer every purpose. It will be best if we choose a lady's face, as it is with the ladies' features, principally, that we will wish to utilize our knowledge, if it be found worthy of use. It is, we will say, a full face, and one with a pleasant look about the features. Now with a crayon make a short downward mark from each corner of the mouth on one picture only, as we will need the other for comparison; then with your finger-end rub in a little white just under the lower lip, adding a trace of shade to the upper lip in the same manner. What is the result? You have a face the owner of which you would think had not an earthly friend. Now, after erasing what you have added, reverse the order of things by placing the light on the upper, the shade on the lower, and drawing your lines upward from angle of mouth, instead of down, as before, and you will find the result reversed also: for the face is found now to be bright and cheerful. By going a little further, and placing two curved lines from base of nose downward, past corners of mouth, with convexity outward, you have a grin that will often prove contagious. A thin piece of paper placed under the lip on the alveolar ridge will add its quota to the expression.

These changes have been effected by a few marks that would be hardly noticeable anywhere else on the drawing, unless about the eyes. If this can be done on paper, can it not be accomplished, say in part, at least, with the face itself? Of course, it is an entirely different matter when we come to put our theory into practice, as it will require that we educate the eye by long and close observation of nature, and teach the hands to follow its dictates.

The lips, of all the features, are the most direct index to the feelings, and the expression characteristic of every face is due almost entirely to the effect of light and shade about the lips. It is (I believe) because we forget this fact, that we often feel dissatisfied with our work even when the patient expresses pleasure with it. I believe, too, that it is owing to the fact that the profession shows want of knowledge, care, or ability in this respect that we meet with so many faces whose owners wear dentures that are blank, or almost expressionless about the mouth. When we hear such common expressions as a beautiful smile, or eloquent lips, do we ever ask ourselves in what does this beauty or that eloquence consist?

Our course of studies in mechanics is, to the best of my knowledge, perfect as far as it goes; but is it carried out to its greatest extent? For instance, we are told to carefully note the play of the lips over the wax articulation; but *what is it* in the play of the features that we are to study? I can but answer for myself. I was expecting to hear *expression* treated in every detail, and felt disappointed when upon nearing a situation where I felt genuine interest, I found that the points which seemed to me of the utmost importance were passed over with a casual remark or two.

I know when I say this that no one will infer that I am trying to pit my limited knowledge and inexperience against years of practical work of my instructors. Perhaps our teachers expected we students to understand without further instruction. Perhaps my classmates, by superior ability, were enabled to bridge over what seemed to me a break in the most interesting part of our course, or it may be that I am expecting too much of dentistry.

Now, the question is, how to proceed in order to derive any professional benefit from the ideas here suggested. As I regard it, the first requisite is to study nature, and study closely. As far as the human countenance is concerned, no one has more opportunity for observation than the dentist. Our business carries with it a certain license, so that we can examine a patient's features critically without giving offence. Unlimited chances are thus offered, and we can watch every face that we work over, and then we must analyze what we see.

Note the general expression, the fulness of the lips, and the tooth development beneath them. Watch where and how the light strikes the face, and what is the result of different lights upon the same features. If any teeth are absent, note the effect upon the expression. Observe color of hair, eyes, and complexion, and then examine the exact shade of the teeth, also the size and shape of the teeth as compared with size and shape of features, form of head, and general build of body. This can be done by a trained eye, while the patient undergoes the usual examination, without suspecting but that your undivided attention is given to the teeth. Then compare this with the next face that presents itself. If this is to afford any benefit to the practitioner, the observation and comparison must be critical. We are too apt to bestow a casual glance, and forget as soon as the patient is gone, whereas we should memorize or make a note of the most important points.

To make ourselves *masters* of the art of light and shade, we must go even farther than this. *We must cultivate a taste for art.* We subscribe for some one or perhaps all of the dental journals—why not for an art journal as well? We try to keep ourselves posted on all the new ideas in our profession—why not mix up a little art with them?

Suppose that we cannot see at first that it is benefiting our work, we cannot deny that it is refining, as well as affording a pleasant change from an occupation that is in many respects disagreeable. Then when we have leisure we can turn our hands to a little modelling.

If we have a small space in our laboratories, why not utilize it by making a bench in a corner that has a good light, and then investing in a few pounds of artists' clay and one or two modelling tools. By an hour's work and the outlay of a few dollars, we have a way of passing our spare moments that will be novel and instructive. For it is in modelling and casting that the effect of light

and shade is made most manifest. If we have doubts of our ability to reap any benefit from modelling, why not try casting, choosing a friend or a patient's face for a subject? Suppose that we try it in this way, our subject being a person who wears a full denture and with a bare face? First make a mould of the face (wax will answer) with the mouth empty. Then one with the plates in position, and then, after building up with wax in different places on the plates, place them in the mouth and make a third mould. Now to cast with plaster. The wax mould will of necessity be thin, so that it is best before casting to build up around the outside of the mould with sand, so that the weight of the plaster, when soft, will not change the shape. Then if you will tint the water with powdered or dry umber and a little vermilion before you mix the plaster, the latter will more nearly resemble the flesh-color. After casting all three, and allowing the plaster to set, if you will remove the wax from each you will be surprised at the entirely different expression on each face. The question is as to where you will find a person who will submit to so much trifling? I have experimented with many different faces, and thus far they have been so deeply interested in the novelty of the work that I have yet to meet the first complaint. In conclusion, let me say that I believe that if our dental brethren who have never tried this, would do so, they would be surprised and pleased with its effect upon their laboratory work. At first, I became discouraged, and thought that I failed more often than I succeeded; but now, when I look back I find that I have not failed. On the contrary, I have succeeded so far that now I am where I can see what can be accomplished if one is persevering. I am convinced that the study of facial expression has helped me wonderfully, and has given a new impetus to work that before seemed monotonous. One thing in which I think all will agree with me is this; that a little art cannot injure us in any way, even if it is æsthetic.

CAMBRIDGEPORT, MASS., October 18, 1885.

COVERING THE HAND WITH SKIN TRANSPLANTED FROM THE CHEST.

BY ALFRED NORTH, M.D.,

WATERBURY, CT.

MICHAEL S——, aged twenty-six, Irish, a brass-roller. On October 27, 1884, while cleaning the rolls while they were in motion, the ends of the fingers of the left hand were caught and the entire hand drawn in to the wrist. The skin was cut through entirely around the wrist, and below this point was so thoroughly crushed and separated from the subcutaneous tissues that it could be peeled off like a glove. The only portions of skin left attached to the hand were a piece about an inch and a half long by one inch wide, between the thumb and the index finger, and the normal skin covering the end of the thumb to midway between the first and second joints; also there were several irregular areas of the corium or true skin left upon the index and middle fingers. The third and fourth metacarpal bones were fractured about their middle; the first joint of the index and the second joint of the middle finger were opened; the ring-finger beyond the second joint and the entire little finger were crushed and virtually dead; the superficial palmar arch was severed and both ends were spurting.

Examination under ether.—After making a thorough examination under ether I decided to make an effort to save as much of the hand as possible.

Dressing.—Both ends of the palmar arch were secured and ligated. A drainage-tube was passed through the hand between the fractured metacarpal bones. The skin of the hand was carefully replaced and secured to that of the wrist by means of silk sutures, the various fragments being secured to each other in the same way. The hand was then wrapped in absorbent cotton, a board splint was applied to the back of the forearm, extending to the ends of the fingers, and secured by a bandage applied to the forearm. The hand and fingers were lightly secured to this by a cheese-cloth bandage. Hot-water dressings were used as the most favorable for maintaining life in the crushed tissues.

Subsequent history.—On the following day all the skin which had been separated from the hand assumed a leaden hue and lifeless appearance. At the end of twenty-four hours all hope of saving it was abandoned, and poultices were applied to hasten sloughing. At the end of a week it had all *gangrened* and sloughed away, leaving only those portions of healthy skin upon the thumb, index, and middle fingers which have already been enumerated.

November 20th.—To-day the periosteum was separated from the remaining phalanx of the little finger, the bone was disarticulated, and the articular surface of the metacarpal bone was removed with bone-forceps. The granulating flaps were united over the end of the bone by fine silk sutures.

November 25th.—The remaining phalanx of the ring finger was separated and removed in the same manner, but the articular surface of the metacarpal bone was left and the flaps were not stitched.

The second joint of the middle finger was exsected and the ends of the bones drilled and held together by a silver wire.

Appearance of the hand (November 26th).—The little and ring fingers are gone, the middle finger has been shortened by the exsection to about two-thirds of its normal length, the first joint of the index finger is exposed, and the distal extremity of its second phalanx extended and dead. The dead portion was removed with the bone forceps.

The areas of skin now found upon the hand are located as follows: The thumb is covered to the first joint on the palmar surface, to midway between the first and second joints on the dorsal surface, and on the side toward the index finger it extends to the bottom of the cleft, where there is a narrow, granulating surface extending from the palm to the dorsal extremity of the cleft, at which point the skin of the thumb and that of the index finger are joined by a band of skin about one-quarter of an inch in width.

The index finger is covered, excepting its outer surface, and the palmar surface below the second joint. On the dorsal surface the skin extends one-half inch on to the back of the hand, and here sends off the band which joins that of the thumb.

The middle finger is covered on the dorsal surface to the first joint, on the palmar surface to the second joint, and on the sides to about the same extent.

Comparing the amount of skin now found upon the hand with that which existed after the injury, it will be seen not only that the perfect skin left at that time has markedly extended, but that the fragments of corium scattered over the index and middle fingers have developed almost sufficient integument to cover these members.

The index and middle fingers were to-day dressed in a common plaster-of-Paris splint, both for support and to ascertain the effect of pressure upon the exuberant granulations.

November 28th.—The thumb and fingers were gently exercised by passive motion. The plaster dressing so much improved the granulations of the fingers that I decided to try it upon the hand. The hand was lightly dressed in plaster, to be left two days.

Treatment preparatory to grafting (December 19th).—Since last note the treatment has consisted chiefly of the application of twenty grains of nitrate of silver to the ounce, or of the solid stick, with balsam of Peru and light pressure by a cheese-cloth bandage. The hand continues œdematous and the granulations exuberant. To overcome this, a plaster-of-Paris splint was fitted to the front of the forearm and palm of the hand, and secured snugly by a plaster bandage. Under this press-

ure the œdema soon subsided and the surface became healthy.

The thumb and fingers have been forcibly exercised to prevent anchylosis.

The contractions and adhesions have been constantly opposed by stretching, pressure, and occasionally by cutting.

A number of small grafts have been planted about the stumps of the little and ring fingers. These were secured in place by several different methods: 1. By the ordinary method of pressing the graft gently until it is embedded in the granulations, and keeping it in place from three to five days by the pressure of the dressings. 2. By passing a thread through the graft and stretching it to the granulations. 3. By passing a thread through the granulations on either side of the graft and tying the ends over it. 4. By making a small flap of granulation tissue with the scissors, and raising it up and placing the graft under it.

Either one of the last three methods is preferable to the first or original method as taught in the books.

In this way a number of skin centres were planted about the stumps and bases of the index and middle fingers.

I have decided to cover the remainder of the hand with skin transplanted from the breast. With this in view, the arm has been applied to the chest in several different positions, and left in each for twenty-four hours, in order to ascertain the most desirable site for the operation, as well as the most comfortable position for the patient during the after-treatment. This course was pursued until a position was found satisfactory for both.

First plastic operation (December 20th).—The patient was etherized, and the breast shaved and cleansed with a solution of bichloride of mercury of the strength of one to five thousand.

An incision was made through the skin, ten inches in length, commencing at the second sterno-costal joint on the left side, passing downward and to the right half an inch within the right nipple. A similar parallel incision was made two and a half inches to the left of this. The intermediate skin was freed from the deeper tissues, its ends remaining attached.

The free edges of the skin on either side of the flap were dissected up for an inch or more, and approximated as nearly as possible, and held so by two silver-wire sutures passing beneath the flap.

After all bleeding had ceased, the wound was cleansed and the hand placed beneath the band of skin. The edges of the skin at the back of the wrist and at the bases of the thumb and fingers were carefully freed with scissors, so as to approximate the edges of the flap to a newly made surface. The granulations were also shorn from the back of the hand, and the adipose tissue from the flap.

The edges of the flap were then applied to the freed edges of the skin of the wrist and fingers, and secured by harelip pins and silk sutures.

Dressing.—Four layers of iodoformized gauze were placed between the hand and the chest, and also upon the back of the hand. A Stromeyer's cushion supported the arm and forearm from the body. The arm was held firmly in this position by four broad adhesive straps in different positions. The thumb and fingers were drawn gently toward the left shoulder and fixed by small adhesive straps.

A drainage-tube was inserted above, and another below the hand. A pete-bag was placed above the hand, another below it, and a third below the fingers. These were covered by absorbent cotton and a Lister-gauze bandage, which passed about the body and covered the entire arm and hand. Lastly, a plaster-of-Paris dressing was applied, covering all except the hand.

After-treatment.—The after-treatment consisted of the application of a bottle of hot water to the dressings over the back of the hand for the first twenty-four to forty-eight hours, and the frequent irrigation of the wound through the tubes. The temperature did not exceed 101° F.

Dressings removed (December 27th).—On the seventh day after the operation, the dressings were removed and the hand exposed. Most of the stitches had cut out. They were all removed except a harelip pin at the middle of the wrist, and another through the stump of the little finger, which had not cut. The flap is all alive, and its edges have united at the base of the thumb and at the corresponding point at the wrist, so that the skin is here continuous from the thumb to the forearm.

The deeper surface of the graft has also united to the back of the hand, with the exception of an area about the size of a silver quarter at the ulnar side of the hand, where there is an accumulation of pus. This was reached by a probe from below, evacuated, and a seton passed through. The wound was thoroughly cleansed and new dressings applied.

Second operation (December 29th).—The graft on the back of the hand is doing as well as I could desire, but the patient is suffering markedly from confinement and the shock of the last operation, which renders it important to complete the work and free the hand from the chest as early as possible, so that he may get out of doors. In view of this I concluded to free one end of the graft at once.

No ether was given. The temperature was 99.5° F., before the operation.

The original incisions were extended upward, making the right edge of the flap three and a half inches, and the left edge two and a half inches long.

These were connected by a transverse incision, after which it was separated from the breast.

The fatty tissue was shorn from it. The palm of the hand was turned upward and the granulations thoroughly removed with scissors. The flap was then applied to the palm and stitched in place.

The edges of the skin of the chest wound just made were freed and slid forward, and secured so by silver and silk sutures and adhesive straps.

Dressing.—The hand was so placed as to rest upon the band of skin below it, somewhat as in a sling, hoping that union in this region might be secured by this means. The dressing in all other respects was the same as after the first operation, except that the forearm was made to rest upon a kind of plaster-of-Paris shelf, lined with absorbent cotton. Temperature, 100.5° F. after the operation.

Third operation (January 3, 1885).—Patient is losing strength and perspires profusely. Condition of both patient and hand is at a standstill. I determined to free the lower flap at once, and separate the hand from the body. The second operation was only partially successful. The proximal one-half to two-thirds of the flap has lived and united to the hand. The remainder is dead, though not separated.

Ether was administered. The original incisions were extended downward, making the flap four inches long, after which it was separated from the body. The fatty tissue was removed with scissors, and the granulations of the hand shorn off as before. The flap was then adjusted and secured in place by sutures.

The dressing consisted of iodoformized gauze, absorbent cotton, and a Lister-gauze bandage. A bottle of hot water was applied to the dressings over the palm for forty-eight hours.

The edges of the skin of the lower half of the chest wound were freed for two inches on each side, approximated as nearly as possible, and secured in place by sutures and adhesive straps. In this way the extremities of the chest wound were closed for about two inches, and the intermediate portion reduced to less than two inches in width.

Chest (January 12th).—Since last note the temperature has ranged from 99° to 100° F., with a correspond-

ing pulse. The sutures have all been removed from the breast. The wound is dressed on alternate days by removing the adhesive straps, cleansing, cauterizing the exuberant granulations, and applying new straps. Although the edges retract considerably when the dressings are removed, yet after new straps are applied they are not separated more than one to two inches.

Hand.—Upon the hand about one-third of the end of the first flap and two-thirds of the second have died and separated, leaving the central portion of the palm bare.

For several days the skin has been stretched around the hand by adhesive straps dove-tailing across the palm, the object being to secure the greatest degree of approximation of those portions of the skin remaining upon the palm.

January 20th.—Patient now walks to and from the office. The skin is still stretched across the palm by means of adhesive straps. The chest wound heals rapidly and is still dressed with straps.

The skin on the back of the hand is now continuous from the forearm to the fingers. The central third of the palm, with a few small areas on the fingers, is still granulating. There is a strong tendency to contraction in the deeper tissues of the palm and fingers, drawing the thumb toward the palm and strongly flexing the fingers. A daily effort is made to overcome this tendency by passive motion and forcible extension.

February 4th.—The contraction of the palmar tissues tends to produce so great deformity of the thumb and fingers that it has been determined to make another attempt to cover the palm with transplanted skin. At first it seemed advisable to do this by dissecting a flap from patient's breast, leaving one end attached and applying this to the palm in such a manner as to make the reflection at the roots of the fingers; then, when union had taken place, to separate it from the body, including enough tissue to be utilized in covering the flexor surfaces of the fingers. But after carefully taking into consideration both the patient's condition and that of the hand, I decided to transplant the graft *en masse* from his brother, and thus be enabled to keep the fingers under daily observation and training.

Accordingly both were placed side by side upon a table and etherized. First I relieved the strong flexion of the index finger and adduction of the thumb by making a deep **V**-shaped incision with the angle toward the palm, one arm terminating in the cleft between the index and middle fingers, and the other between the index finger and the thumb. The index finger could then be sufficiently extended and the thumb partially abducted. The tissues were cicatricial to the full depth of the incisions.

Second, the granulations were carefully shorn from the palm and all bleeding arrested.

Third, a graft an inch and a half long and one inch wide was taken from the brother's side, all adipose tissue shorn off, and applied to the palm, the four corners being secured each by a suture.

Dressing.—The **V**-incision was sprinkled with iodoform and filled with sponge. A sponge was applied over the transplanted graft, and the hand enclosed in a cheesecloth bandage. A hot-water rubber bag was applied to the palm and no splint used.

February 5th.—The dressing caused so much pain that the bandage was removed, and it was found that the skin on the back of the hand would not safely bear any degree of pressure.

May 25th.—The graft transplanted from the brother died. Since last note the treatment has been confined to passive motion, forcible extension, stretching and breaking up adhesions, and the training afforded by splints and adhesive straps. In spite of all this the thumb at this date was drawn well into the palm of the hand. Commencing on the flexor surface of the thumb, midway between the first and second joints, and cutting from side to side, I made seven parallel incisions, one-eighth to one-fourth of an inch apart, and extending as deep as the flexor tendon, which was exposed but not cut. The thumb was then extended as far as it was safe to do, and secured in this position to a dorsal splint extending along the forearm. The tissue cut was thoroughly cicatricial. The incisions were all filled with purified sponge.

June 18th.—The thumb has been decidedly improved by the last operation. The sponges did admirably. The entire space included in the incisions was transformed into a granulating surface to which small grafts were applied. To-day three such incisions were made at the base of the index finger, which was then extended and secured in position in the same manner, the incisions again being filled with sponges. The middle finger resists all orthopedic efforts, and persistently tends to the ulnar side of the hand. The first and third joints are anchylosed and the middle joint is a flail-joint since the exsection.

June 29th.—As the index finger is again becoming strongly flexed, and as the middle finger is hopelessly useless, I decided to utilize the latter in freeing the former. Accordingly I made a deep incision across the palm from the cleft between the index and middle fingers to the cleft between the index and the thumb. I then split the middle finger down to the bone on the palmar surface, removed the entire bone to the metacarpo-phalangeal joint, and applied the remaining tissue across the base of the index finger to fill the incision already made, stitching it in place. Other parallel incisions were made across the index finger, and also across the palm—six in all; also five parallel longitudinal incisions in the palm, extending from the upper of the transverse cuts toward the wrist. These latter were for the purpose of opening out the palm, which was considerably drawn in. A sponge was inserted into the disarticulated joint cavity, and also into each of the cuts.

The index finger was then extended and secured to a dorsal splint, which had previously been secured to the forearm. The thumb was extended and secured in like manner, and the dressing completed by sponge-pressure to the palm.

July 1st.—Temperature 99°. The bandage was removed, and, as far as could be seen without removing the sponges, everything seemed to be doing well.

July 2d.—Temperature normal. The sponge covering the palm was raised and the flap found to be alive and doing well. Moderate passive motion of both thumb and index finger is made daily.

July 4th.—The flap has united by first intention. There is a plaster splint applied to the forearm with a rubber band, attached both front and back, for the purpose of applying elastic extension to the thumb.

July 27th.—The hand has greatly improved since the last operation. There is considerable power of voluntary motion in the thumb and finger, and they can now be made to touch. The constant extension of the index finger has stretched the flap at its base so that now it extends well up on the finger. A splint extends along the dorsal surface of the thumb, and another along the back of the index finger. To these the thumb and finger are secured to overcome the tendency to flexion.

September 9th.—The entire hand is now healed. The thumb is strongly drawn toward the palm. The thumb and finger can be made to touch, but only coarse objects can be picked up.

The patient has to-day resumed work.

Deductions.—In my judgment this case illustrates the following points:

1. The importance of temporary dressings previous to operating, for the purpose of ascertaining the position most favorable for the operation and at the same time most comfortable to the patient.

2. The necessity of determining what form of dressing shall be used before operating.

3. The value of large skin grafts in saving members

and rendering them useful, when otherwise they must be sacrificed or become useless.

4. The time saved in the healing process, the greater part of the hand in this case being covered with healthy skin in two weeks.

5. The advantage of transplanting large grafts, before separating them from the body, over transplanting *en masse*.

6. That the most successful method of transplanting small grafts is either by stitching them in place or by raising a flap of granulations and placing them under it.

7. The benefit of pressure in reducing redundant granulations.

8. The value of multiple incisions in overcoming cicatricial contractions, the credit of which, so far as I know, belongs to Dr. Alfred Post, of New York.

9. The advantage of the sponge in stimulating the growth of granulations and rapidly filling up and healing such incisions.

Were I performing a similar operation again, I should free both ends of the flap from the chest at the same time, thus completing the entire work in two operations. I believe my success would have been better in this case if the work had been completed at the second operation and the ends of the flaps made to support and nourish each other.

The only other case of this kind, so far as I am informed, is one of Dr. W. T. Bull, of New York, which was done in 1884, but to my knowledge has not been published yet.

The great advantage of this method over the old method by many small grafts, is well illustrated by the following cases:

In 1879 Dr. W. T. Bull covered the leg and outer part of the thigh with new skin, by means of small grafts. Twelve hundred grafts were used, and the time occupied was six months.

In a case of loss of the entire scalp, Dr. W. L. Bradley, of New Haven, commenced the use of small grafts on December 1, 1873, and by September 22, 1875, had renewed the scalp, using 795 grafts in all.

Dr. W. Symington Brown, of Stoneham, Mass., also replaced the scalp by means of small grafts. He commenced in 1873, used 2,600 grafts, and completed his work in 1876, three years after the injury.

Dr. Bartlett—deceased—of Waterbury, also replaced the scalp by means of small grafts, the process occupying considerable time, but I am unable to say just how long.

On the other hand, in the cases of entire loss of the skin of the hand, these members were covered with healthy skin transplanted from the chest in the course of two to three weeks.

Combined External and Internal Urethrotomy.—We have received a reprint from the *British Medical Journal* of a paper read before the Lancashire and Cheshire Branch of the British Medical Association, by Mr. Reginald Harrison, who opposes strongly the operation of internal urethrotomy, urging that the most serious consequences may, and often do, result from the stagnation of urine in the wound. The portion of urethra involved in the wound is necessarily paralyzed, and is therefore prevented from expelling the urine, which remains to stagnate and undergo absorption in part. To obviate this difficulty, in cases in which the stricture is seated in the scrotal or pendulous portion of the canal, Mr. Harrison combines the external with the internal operation. He states that he has never seen a rigor or the development of urinary fever after this combined operation. The external urethrotomy, which he performs in order to give vent to the urine and keep it from coming in contact with the urethal wound, is properly described as a perineal puncture, only large enough to admit the passage of a drainage-tube into the bladder. The operation has given most satisfactory results, and will, the author believes, remove most of the danger incident to internal urethrotomy as usually performed.

SYMPATHETIC DISEASES OF THE EYE.

BY C. A. BUCKLIN, M.D.,

Under the above title I wish to call attention to some facts of the greatest possible importance. Having been brought so frequently face to face with this horrible condition known as sympathetic disease, I shudder when I think that the sad fate of the patient is too frequently the result of a failure of some family practitioner or too positive specialist to recognize the intricate nature of the trouble, or the hidden danger which is lurking under a calm exterior.

They fail to fully explain the danger which may follow in time, and complete blindness is the result.

The time required from the injury until the other eye is destroyed varies from a few weeks to forty years. It is impossible to consider in detail the subject of sympathetic diseases of the eye in the limited space a general medical journal can devote to the subject.

The entanglement of a ciliary nerve in a scar, or any other constant source of irritation existing in an eye, as chronic inflammation, calcareous deposit, foreign bodies, scars resulting from a wound. A cataract which is overripe, and has become calcareous, may cause the destruction of the eye, the fellow eye, or both eyes.

I desire to present such illustrative cases as will cause the careful to think, and the careless beware. I present the facts as they exist, not with an intention to criticise, but with a pure desire to do the greatest good.

Case I.—Mrs. B——, aged fifty. In May the right side of the face was covered with an eruption which followed an attack of malaria. The eruption caused a severe burning and itching sensation of the entire right side of the face, which later became covered with a yellow crust. The line of division, however, between the crust-covered right side of the face and the healthy left side, was very sharp. At this stage she consulted a physician, who diagnosed the case as an acute eczema, and treated it as such for three months, when one of the pustules appeared upon the cornea, it ulcerated, the cornea perforated, the iris became extensively attached to the perforation, the eye was lost, and in three months more the other eye was affected with sympathetic disease.

The sharp line of division between the affected and healthy side of the face should have attracted the attention of the physician at once, and caused him to recognize the trouble as a neurosis (herpes zoster).

This case illustrates the importance of recognizing and treating properly neurosis of the fifth nerve. Failure to make a correct diagnosis in this case made a blind woman, when correct diagnosis would have led to a favorable termination of the disease.

Case II.—Mr. M——, aged thirty-three, was chipping cast-iron in 1865 when a piece of iron or chisel struck him on the margin of the cornea. It made a simple, clean wound of the cornea, through which the margin of the iris prolapsed. The eye at the time I saw it looked exactly as if Critchett's operation for displacing the pupil had been carefully performed by a skilled operator—he retained fair vision in the injured eye. He consulted his family physician and several specialists of this city, each and every one of whom were enthusiastic in their explanation of the patient's great good luck in having a sharp piece of iron strike the eye and do so little damage.

The general verdict was, "It is a very fortunate accident; the eye is all right."

Let us now observe the consequences, and see how unfortunate the accident was, and how fortunate it would have been for the patient had the eye been so mutilated that its immediate removal would have been necessary.

All attempts to use his eyes for any length of time fatigued him. His business called him upon the water. In 1873, eight years after the accident, he began to see dark clouds pass over the water, or he would observe a

tremulous or undulating appearance of the water which none of his companions could see. It was three months after he first saw these dark shadows before he saw them again.

The periods became more frequent. Within one year from the appearance of the dark shadows the eye which was not injured was totally blind, and only sufficient vision remained in the injured eye to enable him to read large print with difficulty. No one had considered the injury serious, and no one had warned him of the possibility of the other eye being lost by sympathy.

The operation of Critchett for displacing the pupil has in many instances brought about the same sad consequences years after the patient has passed beyond the observation of the surgeon.

Case III.—Mr. M——, struck in 1859 upon the retina by a sharp piece of steel, which perforated the eye but did not enter the ball. It glanced off. The choroid prolapsed through the wound, and at the time of examination looked like a black pin-head on the whole retina under the conjunctiva.

To show that there is a possibility of every one being mistaken about the consequences which may follow such a simple accident, I casually mention the fact that he repeatedly consulted our most respected authorities on ophthalmology about the black speck on his eye. They assured him that it was a matter not worthy of attention.

In 1873, fifteen years after the accident, his eyes began to tire easily. He began to see smoke in the atmosphere, the vision would periodically become obscure, at last the acuteness of vision became permanently obscured.

All efforts to use the eyes produced an immediate sensation of fatigue, and were disagreeable to him.

He was sent to me by an optician to see if glasses would remedy the trouble.

Upon observing the choroidal hernia I suspected a ciliary nerve was implicated. I cut down by way of experiment and cut the hernia off as close to the wound as possible, from which I freed it as thoroughly as I could. The patient at this time had $\frac{2}{10}$ of normal vision.

The strange feature of the case, which surprised me as much as it will any of my readers, is that in eight days the vision increased to $\frac{2}{3}\frac{0}{0}$ of normal vision, and all unpleasant symptoms had disappeared. Those who propose to open the eye to introduce magnets or transfix the choroid with needles, should remember that this case illustrates the possibility of doing a damage which may, fifteen years later, cause both eyes to be lost, although the original object for which the magnet or needles were introduced was well accomplished and successful. Such patients cannot be too thoroughly warned as to the possibility of danger years afterward, and the symptoms which indicate its approach, as fatigue, mist, dark shadows, flashes of light, etc.

Case IV. illustrates an example of the careful specialist, who is thoroughly aware of the danger, while treating a child on the *expectant* plan. The child has a herpes of the cornea, which sloughs with a large prolapse of the iris in the wound. This is followed by cyclitis, for which she is being treated, and the other eye is being kept under observation. The mother is told to bring the child back in four weeks, as the cyclitis in the injured eye has quieted down. In six weeks she returns with the child, and imagine the mental chill which must pass over one when he looks into the *uninjured* eye and sees delicate cyclitic membranes stretching entirely across the field of vision. It is too late to enucleate the offending eye—the child is blind.

There was no warning in the shape of a complaint from the child. There was no decided injection of the eye to attract the attention of the mother or physician.

Specialists are frequently deterred from doing their duty by the outside pressure of parents, friends, physicians, and dishonest or sometimes ignorant "eye-doctors," who are willing to give a favorable prognosis on no other grounds than a desire to please the family.

I believe that in children upon whom we cannot rely for early information regarding symptoms in the other eye, it is the duty of the specialist to strongly advise the removal of every eye which decidedly endangers the fellow eye.

Case V.—Mr. R——, at twenty years of age, cataract found in one eye, from unknown cause. At fifty, sympathetic irritation appeared in other eye in the form of flashes of light. Enucleation of offending eye arrested further development of disease in uninjured eye. The lens was calcareous, and calcareous deposits were thickly distributed through the ciliary body. There were evidences of an old cyclitis, with extensive detachment of the retina. The cyclitis, not being traumatic, was evidently specific.

Case VI.—Mr. L——, struck in the eye with a cowhorn during boyhood. At the age of sixty, the other eye, which has behaved well during this time, is affected sympathetically, the development of which affection is announced by dark shadows followed by flashes of light and entire loss of the uninjured eye. Cyclitis and calcareous deposits are found in the injured eye.

The last two cases bring us to a practical point regarding cataract extractions.

How often has the following rule been laid down to students of ophthalmology?

Never remove a cataract before it is ripe—meaning as long as fingers can be distinguished. Never remove a cataract from an eye when it is plain that no visual improvement can be attained, unless the patient desires it done for cosmetic purposes.

Never remove a cataract as long as there is good vision in the other eye.

In all cases of cataract, except the congenital variety, the crystalline lens is undergoing progressive atrophy—the vitreous is becoming fluid, and the intra-ocular blood-vessels are becoming weak. Calcareous deposits are sure to form in the hypermature cataract.

Is it not better to disregard all these rules and remove the diseased lens from the eye at such time as it can be removed with the greatest safety to the patient? A calcareous lens is a dangerous thing to have in an eye, and also a very dangerous lens to remove by the usual method of opening the capsule, the calcareous débris being liable to fall into the eye during the evacuation of the lens. I have seen both eyes totally lost within ten weeks after such an accident. The operated eye was destroyed by cyclitis, and the eye not operated upon was destroyed by sympathetic disease. If it can be seen that a lens is filled with calcareous deposits and it is to be removed, it is better to remove it in its capsule entire. The removal of the lens in its capsule is a dangerous operation under the most favorable circumstances, and still more liable to cause loss of the vitreous, and intraocular hemorrhage in cases where the lens has remained in the eye till it is filled with calcareous deposits. Having waited till the lens is in this state one is between two fires, and it is impossible to judge which is the more dangerous, the chance of dropping calcareous deposits in the eye by the ordinary method of extraction, or the chance of causing intraocular hemorrhage, or cyclitis, by the violence done the eye in attempting to remove the lens in its capsule. I prefer to remove the lens as soon as they cannot count fingers at a greater distance than two feet. In the majority of cases this avoids all serious complications. The lens comes out easily. There are no calcareous deposits in it. The vitreous and intraocular vessels are in a healthier state than they ever will be at any subsequent time. When I see some specialist of experience who is willing to have the lens and capsule torn from his own eye, I shall believe that this method of removing the lens in its capsule has one enthusiastic and honest advocate. I never will do an operation on a patient's eye that I would not ask a colleague to perform on my eye if I were the patient.

In iritis we sometimes see a nodular appearance of

the surface of the iris: this is due to circumscribed portions of the iris being so scaled down that local cavities are formed in which fluid accumulates and lifts the iris, forming an elevated nodule, of which there may be several. Such eyes, as visual organs, are of no value; they are almost sure to set up sympathetic disease in the other eye, the only preventive measure against which is enucleation. If the family do not indorse this operation let some kind-hearted colleague take the case and also the responsibility. Iridectomy in these cases is too uncertain to be encouraged.

When the entire margin of the pupil is fast to the lens, or cornea, iridectomy is usually all that will be required to make the offending eye safe. Having illustrated what may happen to those who do not appreciate the dangers which may arise from sympathetic disease, we will mention two cases which illustrate what the over-zealous specialists do occasionally.

Mrs. C——, aged fifty, has acute syphilis; right eye develops plastic iritis, with multiple adhesions of the margin of the iris. Four months later simple plastic iritis breaks out in the left eye. She visits two of our city eye institutions. The pupil of the last affected eye dilates readily under atropine, with one marginal attachment of the pupil to the iris. The disease of the second eye is called sympathetic. Enucleation of the right eye is most urgently insisted upon at both institutions.

I freely confess that I am not so bold as to advise the removal of an eye that still has a good visual field, because plastic iritis has b oken out in the fellow-eye without any premonitory symptoms.

The syphilitic eruption being in a most flourishing condition, is it not more judicious to call the iritis of the second eye a specific iritis, and to treat it as such energetically, rather than enucleate one eye before you are sure which eye will turn out to be the better, and before you are sure that the enucleation of the eye will not have a disastrous effect upon the fellow-eye, which is already in an irritable and dangerous condition?

It must also be remembered that such eyes, as a rule, do very well without enucleation.

Mr. R——, aged twenty-five, had specific iritis of one eye, which caused extensive pupillary attachments of the iris to the lens. The pupil appeared blocked with a mass of exudation. Several weeks later the second eye was attacked with plastic iritis. The advice given by several specialists was to enucleate at once. He was treated for syphilis and iritis. At the end of four months the eye with which he could read was the one the enucleation of which had been strongly advised.

A single adhesion of the iris to the lens is more dangerous than two or more adhesions so situated that the movement of the iris is limited; such eyes are only to be operated upon when sympathetic irritation appears in the fellow-eye, or the attachment of the iris to the lens becomes complete and water-tight. This can only be determined by the iris appearing "crater-shaped," thus proving that fluids can no longer escape into the anterior chamber.

Adhesions of the iris to corneal wounds are more liable to be followed by sympathetic trouble than adhesions of the iris to the lens.

Blood-letting Extraordinary.—M. Thevenau, of Nivernais, according to the *Revue Médicale*, had under his care the wife of a sheriff named Gignault, twenty-four years old, whom he bled, in the course of nine months, from September, 1726, to June, 1727, 3,904 times. The woman still lived, and was bled 651 times more in the next six weeks. Bleeding, it appears, was the only means of giving the woman relief, and it was accordingly practised most industriously for three and a quarter years, the number at the expiration of that period reaching the very respectable figure of 26,230. It is not stated why the phlebotomy was discontinued at this time, but possibly the patient died.

Progress of Medical Science.

Bromide of Camphor.—This drug was first introduced into the field of practice in 1871, and possesses, in spite of its comparative youth, an ample literature, of which we will only refer to the most recent and therapeutically important works (*The Therapeutic Gazette*, November 16, 1885). Not long ago Valenti y Vivo called attention to the physiological antagonism existing between the monobromide of camphor and strychnine, a fact which has a toxicological value. Lienhart contested the hypnotic virtue of the drug which Hammond upheld. The latter physician cited a case of delirium tremens in which he employed this remedy. After the eighth dose, Hammond says, the patient slept for four hours. After awaking he obtained the remedy again, and after six doses he slept for six hours. Warren, of New York, as long as ten years ago used the bromide of camphor with good results in typhoid fever, and declared that it exercised an actual influence over temperature and circulation. Petrowitz employed the drug in numerous cases of hysteria, chorea, cardiac palpitations, and nocturnal erections with satisfactory results. He mentions the case of a medical student suffering from nocturnal erections and following pollutions, who was treated with bromide of potassium without success, but was promptly relieved by bromide of camphor. Gubler claimed to have obtained remarkable sedative effects with capsules of bromide of camphor in genital excitation, and especially in blennorrhagic priapism. Camphor, says this author, does not ordinarily traverse the kidneys, but in the form of the monobromide it can be made to do so. Marm employed the drug in mental diseases, and more recently Hammond in hysteria, in doses of two to three grains given every two hours after the paroxysm. In the latter affection it is especially suitable when ether and chloroform are contraindicated. Nothnagel and Rossbach recommended the remedy against nervous excitation of the cardiac and genital systems. Fonssagrives, reviewing the various therapeutic uses of the drug, calls it an antispasmodic, an anaphrodisiac, and a general nervous sedative. Rolland and Mills furnish further testimony to the useful services of the drug in affections of the nervous system. Quite recently it has also been tried in chorea with promising results.

Etiology of Floating Kidney.—It is a well-known fact that movable kidney is found with greatest frequency in multiparæ, and the explanation usually given is that it is due to laxity of the abdominal parietes. But this does not account for the fact that the organ displaced is usually the right one. In the *Revue Bibliographique des Sciences Médicales* of October 31, 1885, Dr. Eugène Martel puts forth the theory that the displacement is caused by the movements of the fœtus in utero. At the end of the fourth, or during the fifth month, the fundus uteri reaches the lower border of the kidneys, and as the organ is usually inclined to the right, it is the kidney of this side that is pressed against. It is at this time, also, that the movements of the lower extremities of the fœtus begin, and as the left occipito-iliac position is the most common one, the right kidney is in position to receive frequent blows from the knees and feet of the child. Dr. Martel states that he has found movable kidney in several instances shortly after a pregnancy during which the fetal movements were especially active.

Dermatitis Exfoliativa in the Adult.—Dr. Funk relates a case of generalized dermatitis in a woman after childbirth. The eruption had all the characters of eczema: papules and pustules, isolated and in groups. Here and there were bullæ of varying size, containing micrococci arranged in small chains. The case recalled in its general characteristics those of dermatitis exfoliativa neonatorum reported by Ritter.—*Revue Bibliographique des Sciences Médicales*, No. 22, 1885.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 9, 1886.

THE QUESTION OF GOVERNMENT PATRONAGE FOR MEDICAL INVESTIGATION.

AN unexpected aspect of the present public interest in the investigations of Pasteur is the awakening of the people to the fact that in this country there might be wider opportunities for profound study of physiology and the workings of disease.

Two great requisites are needful—time and money. That the hydrophobic virus has required two years for its elaboration, gives some inkling that art is long and time is fleeting. It is seldom that the medical scientist has both time and money at his command. The student with a strong bias toward investigating the deep problems of life, and who would gladly shut himself up in a laboratory to attempt their solution, finds himself obliged, after graduation, to go out into the world to win his bread. The process soon dispossesses him of his original enthusiasm; he grows rusty on his once favorite themes, and others more commonplace come in to absorb him. He looks after Mrs. Smith's rheumatism, and takes an interest in Brown's baby, as, rotating through the orbit of childhood, it encounters the diseases peculiar to each succeeding phase, while humanity at large suffers because the grand discoveries which at first beckoned on their Columbus remain still a part of the great unknown.

Americans are peculiarly adapted to become investigators in physiology and the art of healing. Untrammelled by traditions, with their quick perception and power of invention, with their readiness to absorb others' ideas, and to build upon and to enlarge them, if proper encouragement were given them, the world would look to them, as it now does to France and Germany, for the elucidation of wonderful theories relating to disease and human welfare.

Europeans have made strides where we have crept, because government patronage has been extended to the anatomist and the physiologist. What the effect of government patronage would be in this country has been illustrated by its effect in astronomy. A few decades ago this country was not thought of when this science was mentioned. The Government built observatories and took it under its protection; the result is that today we make as many celestial discoveries as any nation; our telescopes are the largest and the best, and are sent for to furnish European observatories.

If the Government would provide laboratories for biological and physiological investigation, it is safe to say that the discoveries of Americans in the terrestrial world would be as great as in the celestial.

In order to combat disease correct theories are necessary, based on absolute fact as far as possible. The microscope and the test-tube have revolutionized the science of medicine. There is no department in the treatment of disease but what holds out alluring promises of reward to the investigator. Since the welfare of the people, nay, their very lives, depend on the working out of these theories, every means and every encouragement should be given to those who attempt it.

It may be alleged that it is not the province of a democratic Government to patronize the arts and sciences; that it does very well for the more arbitrary rulers of Europe. To protect the interests of its people is surely the highest duty of any Government, monarchical or republican. To promote the knowlege of physiology, anatomy, and the healing of disease is to make more competent physicians to cope with the multitudinous ailments which flesh is heir to.

If an American wishes to fathom the deepest mysteries revealed by the microscope, to plunge into the deepest study of biology, he goes to Europe. Marey could never have made his magnificent studies of the circulation of the blood if the French Government had not given him its patronage.

Private munificence does much for arts and sciences in this country, and will probably do more. We are sure, in the fine arts and in medicine, even if entirely neglected by the Government, to do something one of these days worthy of the nation. If Pasteur's interesting experiments in hydrophobia should prove but the baseless fabric of a dream, they will have done much for us in that they have opened the eyes of the people to the fact that the medical scientists of America lack money and patronage to carry out investigations necessary to make a grand progress in the treatment of disease.

PARIS PHYSICIANS AND THE NEXT INTERNATIONAL CONGRESS.

WE publish below a communication from Dr. Johnston, of Paris, regarding the International Medical Congress. Dr. Johnston occupies a leading position among American physicians at Paris, and his letter should be read with attention:

"TO THE EDITOR OF THE MEDICAL RECORD: SIR—A considerable number of Paris physicians of eminence desire to attend the International Medical Congress appointed to be held at Washington in 1887, and have been making preparations to that effect.

"But the distance is great, especially to gentlemen little habituated to voyages of that magnitude; the total time consumed makes a large blank in a man's yearly labor; and to undertake such an enterprise they ought to have as much time for both reflection and preparation as it is possible to give them.

"May I be permitted to say, therefore, that I feel sure that it would be rendering these gentlemen a very great service, in fact, that it is a duty that ought not to be deferred a day longer—if there be any one with sufficient authority to speak in the matter—to announce at

once in the medical press, whether the Congress is to meet as agreed upon at the last Congress at Copenhagen.

"I have the honor to be, etc.,

"W. E. JOHNSTON, M.D.

PARIS, December 15, 1885.

If we were to give to the foregoing inquiry an answer unreservedly in the affirmative, we should be misrepresenting matters to our Parisian confrères. It is announced positively and officially that there is to be an International Medical Congress. But we must add to this that the American profession is seriously divided over the matter of its management, and that a considerable part of the best men of the profession have been excluded, or have been forced in self-respect to withdraw, from all connection with it.

We are glad to state, however, upon authority, that efforts for a compromise are now being made, and that there are a number of prominent gentlemen in this city, who have heretofore held aloof from the Congress, who are willing to join hands with the present management if such concessions are made as will enable them to do this properly.

We shall be able, probably within a fortnight, to say whether these hoped-for arrangements have been made, and we shall make the announcement to our French confrères at that time.

If they are not made, and the present dissensions and disagreements continue, we cannot conscientiously advise foreign physicians to come over here.

EXAGGERATED FECUNDITY.

WE constantly notice in the daily newspapers paragraphs of a quasi-medical character that are quoted from country journals. They usually relate to cases of ministers or remarkable cures without medical aid, but always some sensational story, which makes a good newspaper item, and on this account is copied by all the daily and weekly journals throughout the country.

Recently such an item was published in a leading New York daily journal, and we have since observed it in exchanges from Chicago, Washington, D. C., and it is probably well on its way to more remote points of the Union.

It was the very simple statement, copied from the newspaper published at Napoleon, O., that the wife of William Friend, residing near that city, had presented her husband with five children at a single birth, and that the mother and all the children were doing well.

This story bore the guise of truth, as the name of the unfortunate parents were given, the locality, and authority. We, however, thought we would make this a test case, so as to arrive at the general truth of such statements.

In reply to a letter to the postmaster of Napoleon, O., he (Mr. S. C. Haag) stated that "this occurrence *should* have happened with a family living at Holgate, a town ten miles from here. William Friend himself denies the report, notwithstanding his neighbours claim the statement to be true."

This rather complicated matters, as William Friend, the victim, was surely a good authority on the subject, and ought to have been cognizant of the rather sudden addition of five blooming children to the family circle; but as the local Paul Pry and neighboring gossips still stoutly maintained the fact to be true, it remained an open question whether William Friend, from motives of modesty or prudence, had not withheld the truth. Many a man before him, the hero of a less glorious achievement, had declined public recognition, preferring to pursue quietly the even tenor of his way; besides, William Friend, if a poor man, might have dreaded the effect of the news on his creditors.

The postmaster, however, did one good service in sending the name of the medical attendant who presided at the quintuple delivery of the five little Friends.

He proved to be Dr. J. Townsend of Holgate, O., and in reply to a letter of inquiry, he promptly furnished a solution of the mystery.

From him we learn that, four years ago, Mrs. Friend honored her husband with triplets, whose entrance into and exit from this world was a contemporaneous event. Recently this lady, still despising the orthodox maternal instinct, which is usually all sufficient to satisfy the most ambitious and aspiring husband, gave birth to twins, who still survive.

Such fecundity as five children at two births was apparently a thing to be despised by a Western local editor, so to provide a good sensational item he lumped the aggregate of all the births into one great appalling maternal catastrophe. In other words, he determined "to mix those babies up," although Mrs. Friend, in the exercise of a wise discretion, took a breathing time of four years between her great efforts.

The result of this little investigation among Friends will probably serve as a caution to those who gather medical and scientific facts from lay journals.

M. PASTEUR.

M. PASTEUR is certainly the most astute of scientists. He has developed a protective virus which it takes some two years to manufacture, consequently he is safe for that length of time, at least, against all rivals who would wish to corroborate or otherwise the validity of his method. This virus is employed to prevent a disease which, in the great majority of cases, never develops anyway in the patients subjected to experiment. It is probable that not more than fifteen per cent. of persons bitten by genuinely rabid dogs get the disease.

These facts make M. Pasteur's position, as the inventor of a protective virus, quite a safe one. The distinguished savant is making it still more so by announcing that no others need attempt to manufacture the virus, as he can treat the whole world of bitten people. This speaks volumes for the rarity of rabies in man, or the quantitative resources of Pasteur's laboratory. After a human being is bitten, the disease generally develops between four and twelve weeks. In some cases, however, it has been known to appear within the second week. Unless the people of India, Africa, and China, then, have more than the circumnavigatory abilities of Mr. Phineas Fogg, we hardly see how Professor Pasteur can treat the world.

All this may seem somewhat captious criticism, but

unfortunately this is not the first time that Pasteur has announced, as wonderful discoveries, prophylactic inoculations that have been practical failures. We have every desire to do the distinguished experimenter justice, and will join in ascribing to him the most unstinted honors when he proves that his present jugglery with rabbits' cords amounts to something.

MISTAKEN CRITICS.

We observe that recently some of our usually quiet and mainly scientific and analectic contemporaries have come out with editorials upon the International Medical Congress controversy. This they have characterized as "indecent," "disgusting," "vituperative," "disgraceful," etc.

Such criticisms are untruthful, and do injustice to the medical press of the country. The fact that a quarrel exists is humiliating and unfortunate, but the controversy has been carried on without the use of language that could be called either "vituperative" or "indecent." So far as our own columns are concerned a strict regard has been paid to the use of Parliamentary language, the construction of admittedly rhetorical periods, and the elasticity of journalistic amenities. Most of our contemporaries can safely say the same thing. If there has been anything "indecent" or "disgraceful" it has not been in the mode of the controversy, but in the fact of its existence.

THE NEW YORK STATE MEDICAL SOCIETY.

The annual meeting of this society at Albany will soon take place, and we learn that a very large number of interesting papers have already been promised. We have no doubt that the prospects of a profitable meeting, and the feeling of loyalty to the old State society, will cause a large attendance.

It is quite time to consider the question, however, of some radical change in the society's organization, and in its time and place of meeting. The society, when chartered, and for long years afterward, held some controlling power over the practice of medicine in the State. Its organization was based on this fact, and membership was made a thing not easily attained. The society now has practically only scientific and social functions. The question arises, therefore, whether it would not be wiser to abandon its present elaborate machinery and throw the membership open to all, as is done by most other State medical societies. There are many reasons for believing that its popularity and usefulness could thereby be greatly increased.

THE COMMITMENT AND MANAGEMENT OF THE INSANE.

Two reforms in connection with the insane are urgently needed. One of these relates to the methods of commitment, the other to the treatment of the acute insane.

We have already alluded in these columns to this subject, but a constant reiteration is necessary. Practising physicians in this city who are called upon to commit the insane are often subject to vexatious delays and great personal annoyance. The physician generally has to go down town and await the pleasure of clerks and judges. Certain judges, we are informed, refuse to sign certificates in any case. The doctor is often obliged to fee the clerks in order to facilitate matters. There should be certain judges designated whose duty it would be to sign the certificates, and whose services could always be had without delay.

The manner in which the insane of the city are herded together, without receiving careful examination, or watchful and scientific medical treatment, is simply outrageous. As matters stand now, an insane pauper might just as well be boxed up in the Tombs as sent over to Blackwell's or Ward's Islands. The medical treatment amounts to nothing. It is quite time that some change be initiated. The chronic insane should be sent off to some country asylum, and sufficient room be given for the proper care of the acute cases. Upon treatment rightly given at these stages often depends the individual's future health and usefulness.

THE PREVALENCE AND CAUSES OF HERNIA.

The subject of hernia is one of such permanent interest that we offer no apology for calling attention to a number of facts regarding it which have been gathered together by Mr. R. J. Pye-Smith, although many of them are not particularly new.

Hernia occurs in about 1 in 25 of the population, but it is more frequent in Germany (1 in 13 adults), and least frequent among the Irish. One death in every 500 in England is due to hernia; and out of every 5 cases of strangulation 1 is fatal. Again, 1 case in every 10 suffers strangulation at some period of its existence, and hence 1 case of rupture in every 50 is ultimately, according to Dr. Pye-Smith, fatal.

Half the cases of strangulated hernia admitted into hospitals are inguinal, of which about two-thirds are reduced without operation, and one-third are operated on, with a mortality of forty-eight per cent. About one-seventeenth are umbilical, of which also two-thirds are reduced without operation, and one-third are operated on, with a mortality of fifty per cent. The remainder (nearly half the cases) are femoral, of which one-third are reduced without operation and two-thirds are operated on, with a mortality of forty per cent.

Thus it will be seen that one-half the total cases of strangulated hernia are reduced without operation, and half are operated on, with a mortality of forty-three per cent.

In the male inguinal is over twenty times as common as femoral hernia, while in the female femoral is somewhat (though not much) more common than inguinal.

With regard to age, Dr. Smith finds that inguinal hernia in both sexes commences far more frequently during the first year of life than it does during any subsequent year. It is found, too (Birkett), that half the cases of inguinal hernia admitted into hospital wards are of the congenital form. And again, femoral hernia occurs as a mere curiosity before puberty, but in each of the years between the ages of twenty and fifty, it develops, in women, with great frequency.

The exciting causes of hernia are almost exclusively such as put pressure on the contents of the abdomen, such as accidents causing a squeezing of that cavity,

straining, holding the breath for muscular exertion, especially in lifting weights (in which position the anterior abdominal muscles are at a disadvantage), coughing, vomiting, etc. Hence we find women affected in parturition, men in stricture of the urethra, and both sexes in bronchitis and in constipation. In male children Dr. Smith thinks that far the commonest exciting cause is the straining produced by phimosis. Mr. J. A. Kempe found, at the Ormond Street Hospital, that 3 out of every 5 cases of phimosis were ruptured, and among Dr. Smith's cases of hernia in male infants he found that 4 out of every 5 had phimosis. It is curious that this coincidence appears to have attracted so little attention. It is scarcely, if at all, mentioned in the text-books, and except for Mr. Kempe's communication to *The Lancet* (in 1878), Dr. Smith has seen only passing references to it. It is, however, a point of much practical importance, and may afford an additional reason for performing circumcision or dilating the prepuce in all cases of congenital phimosis, whether hernia is present or not.

DR. SUSSDORFF VINDICATED.

We are happy to learn from official papers before us that the long and annoying suit brought by Mrs. Lydia C. Cocks, of this city, against Dr. Gustave E. Sussdorff and another, for damages at the rate of $50,000 for loss of services of her daughter Clara, through malpractice at the hands of Dr. Sussdorff, has been decided against the plaintiff, and in favor of both defendants. Dr. Sussdorff has not only received a full and clear acquittal from the court, but we notice with pleasure that his treatment was pronounced to have been in every way proper and skilful, and that the patient was not injured, but greatly *benefited* by it. We have always believed such would be the result of the case, knowing, as we do, the doctor to be an honorable gentleman, as well as a skilful and conscientious physician.

We heartily congratulate him upon this final disposition of so annoying a case.

THE FUTURE OF CREMATION.

The literature on this subject has already become quite voluminous. That this method of disposal of the dead will become the method of the future, in cities at least, there seems at present little reason to doubt. It will meet the usual obstacles from old customs, prejudice, and preconceived opinion. But twelve years ago it was demonstrated by two Italian physicians, Brunetto and Gorini, that the body could be reduced to ashes without wounding the feelings of the most susceptible or fastidious; without sight, sound, or smell. The first great step was then taken. Cremation was demonstrated.

Since that time public opinion has steadily grown in its favor. Italy has led in this respect; but in our own land, nay more, within a few miles of us, cremation is now of almost weekly occurrence. Four bodies have already been burned at Fresh Pond, and, if the daily prints are to be believed, with excellent satisfaction to the friends of the deceased.

It is somewhat curious to note the grounds on which cremation has been opposed. The great argument in its favor has always been the sanitary one. From the very outset no one has disputed this or attempted to gainsay it; indeed, any attempt so to do would have been flying in the face of scientific facts. The observations of Pettenkofer, concerning ground-air and water, and the relation of their fluctuations to the outbreak of zymotic diseases, have proved the truth of Sir Henry Thompson's conviction that "no dead body is ever placed in the soil without polluting the earth, the air, and the water, above and about it." Some have declared that the abandonment of inhumation would rob the earth of its due allotment of nitrogen. The reply of the cremationists has been, that while the nitrogen of the incinerated body passes into the atmosphere in a gaseous form, it is by the rain eventually deposited in the earth, just as surely and just as effectually as if inhumation were practised. Some over-anxious orthodox people have feared that cremation would in some way show irreverence for the Christian doctrine of the resurrection, reasoning from an entire misapprehension of the relation between the spiritual and the physical. They have been speedily silenced by the crushing question of the orthodox Lord Shaftesbury: "If burning the body interfered with the resurrection, what would become of the blessed martyrs?" There is no doubt but that cremation was practised in the early days of Christianity. A careful study of the centuries shows it to have prevailed somewhere almost continuously since. Evidences are plain of its existence among the Swiss, in the eighth century, and among certain tribes of North American Indians at a somewhat later period. So in this, as in so many other matters, our greatest advances are only in the line of a return to the manners and customs of our progenitors.

The abolition of much of the expense connected with the present mode of burial is not the least advantage attendant upon cremation. The cost of single graves in the public lots of nearly all the cemeteries about New York is above the means of many poor people, and if they are not the recipients of some charitable organization, their dead must go to the Potter's Field. Even if cremation were to be in these cases at public expense (as will doubtless be the case in the future), it would be some comfort for the friends to know where the ashes of the dead were kept; for a public columbarium is much less harrowing to the feelings than a public burial-place.

Another curious argument advanced in favor of cremation is that the final religious services would be performed under cover, and that friends and relatives would not be exposed—as is now often the case—to the danger of taking cold and contracting thereby a serious if not a fatal illness. This argument is not without some force. From a sympathy and desire to show proper reverence for the dead, many persons expose themselves at funerals to the weather who, under other circumstances, would exercise greater caution.

Of course, no such subject could be discussed at large without stimulating some would-be paragrapher into attempts at humor. These have varied from the account of the small boy who was sent with a tin pail by his mother to the undertaker to learn "if dad was cremated yet," and if so to bring home his ashes, to that sentimentalism which has led some afflicted ones to plant flowering plants in the ashes of their deceased, and presumably water them with tears of sorrow. We are told

in a volume on cremation that this latter occurrence has actually happened. Looking upon the matter of cremation in a sober light, we must admit that it has already gained a foothold in this country. No one has dared to oppose it on scientific grounds. All are convinced of its utility from a sanitary point of view.

ALLEGED MISUNDERSTANDINGS WITH REGARD TO THE INTERNATIONAL MEDICAL CONGRESS.

CERTAIN of the gentlemen now having in charge the conduct of the International Medical Congress are hugging to themselves the delusion that it is simply a want of true understanding of matters that keeps up the present discord.

They should disabuse themselves of this idea at once.

It is perfectly well known that the Congress is now in charge of an Executive Committee, consisting at present of nineteen gentlemen. Three more names will be added when Presidents of the Sections of Physiology, Pathology, and Gynecology have been obtained, and the total membership is limited to thirty.

This Committee fails to gain support or confidence because it represents, not the profession, but the narrow policy and political methods of the American Medical Association —a policy which overturned the work and affronted the dignity of the original Committee, and because no confidence is felt that it will carry on the management of the Congress on liberal principles, recognizing scientific merit apart from any Code affiliation.

If the members of this Committee will personally take the trouble to make concessions which will remove this distrust, the organization can go on. But they must do more than tender a sop here and there, with no definite assurance as to their future policy.

News of the Week.

TOXIC EFFECTS OF COCAINE.—Dr. Thomas R. Pooley, of this city, writes: "In your issue of the 26th ult., p. 716, appears an abstract from the *British Medical Journal*, which in turn is an extract from a communication from Dr. Ziem, of Dantzic, to the *Allgemeine Medicinische Central-Zeitung*, on the 'Toxic Action of Cocaine.' This author reports a case in which toxic symptoms occurred from the instillation of two drops of a four per cent. solution of cocaine to the eye of a man aged forty. He then refers to seventeen cases which have been recorded in ophthalmological literature, and gives the authors' names, with the number of cases recorded by each. Three of these observations are credited to Dr. H. Knapp, of this city. My purpose in this communication is to state that, in all probability, one of the three cases credited to Dr. Knapp in reality was observed by me and referred to in his paper, by my consent, upon a written request of his to be allowed to do so. Since, so far as I am aware, mine was one of the earliest observations of the toxic effects of cocaine when dropped into the eye, it seems to me important to briefly refer to it again. November 14, 1884, preparatory to operating upon a healthy girl for strabismus, I instilled one or two drops of a four per cent. solution of cocaine. In a few minutes after there followed such extreme dizziness that the patient did not dare to try and rise from her chair lest she should fall. She did not lose color, had no nausea, but broke out in a profuse cold perspiration, and the dilatation of her pupil was greater than I had ever seen before from this drug. This case was referred to in a paper read at the Medical Society of the County of New York, February 3, 1885, and since published in their 'Transactions.' It was also published in the *New England Medical Monthly* for March, 1885, and is referred to by Dr. Knapp in his lengthy paper on 'Cocaine and its Use in Ophthalmic and General Surgery,' published in his Archives, volume xiii., Nos. 3 and 4, p. 442."

JOURNALISTIC CHANGES.—We learn that *The Analectic* will in future be edited by Dr. R. W. Amidon. *The American Practitioner* and *The Louisville Medical News* will hereafter be merged into one, and will be called *The American Practitioner and News*, edited by Drs. D. W. Yandell and H. A. Cotell. It will appear every two weeks.

NEW YORK POST-GRADUATE MEDICAL SCHOOL.—We are informed that the report that the Post-Graduate Medical School does not intend to take women physicians as matriculants is incorrect.

THE HOSPITAL SATURDAY AND SUNDAY FUND.—Up to the first of the week the total amount of the hospital Saturday and Sunday contributions for 1885–86 was nearly twenty thousand dollars. It is stated that the total amount promises to be larger than it was last year.

CHOLERA STILL ACTIVE.—As late as December 15th last cholera was reported still present in certain districts of Italy.

PASTEUR'S INOCULATIONS.—Pasteur has now treated seven Americans for the purpose of preventing hydrophobia. Of these it is not positively known that a single one of them was bitten by a rabid dog, unless it be Kaufman. The daily papers of the present week announce that the dog which bit him bit another dog, which latter has had signs of hydrophobia.

DR. C. L. DANA has been appointed Visiting Physician to Bellevue Hospital. An honor worthily bestowed.

DR. JOHN C. FAIRFAX, a practising physician of Prince George County, Md., is by descent and law the eleventh Lord Fairfax. He is also Lord Camerden. The first title is Scotch, the second an English title. Dr. Fairfax is an American citizen, and does not aspire to such baubles as an hereditary peerage bestows without estates to sustain them.—*New Orleans Times-Democrat.*

MR. AM ENDE, the Hoboken druggist who was put on trial for causing the death of two persons by administering morphine instead of quinine, has been acquitted. The defence set up was that the accident that resulted in the deaths was such as might have occurred in any drug store, and that outside of that Am Ende was suffering from mental overwork that made him absent-minded and led to his doing mechanically the things he had to do. After deliberating an hour and a half the jury rendered a verdict of "Not guilty." No doubt the lesson has been severe enough without the enforcement of a legal penalty. We are glad that Mr. Am Ende was set free. At the

same time it is quite evident that the defence set up was utterly frivolous and invalid. The defendant escaped no doubt because the jury did not think that he deserved the penalties of manslaughter. Perhaps it might be better if the law allowed some milder penalties for punishing the carelessness of druggists than those which now exist.

The Attack on the City Board of Health.—Much disappointment is felt in medical circles over the action of the Board of Estimate and Apportionment in cutting down the appropriations for the City Health Board, and for the Street-Cleaning Department. While several Departments, including that of Parks and of Police, receive increased amounts, that for the Health Board is cut down from $469,758 to $319,800. The Street-Cleaning Department also receives $100,000 less than last year.

Governor Hill and the State Board of Regents, and the State Board of Health and of Charities.—In his annual message Governor Hill thinks that no reason for the continued existence of the "Board of Regents of the University" exists, and he recommends that it be abolished and its powers and duties relating to schools be transferred to the Department of Public Instruction. He also recommends the abolition of the State Board of Charities, and the creation of a single-headed department as a substitute, the official to be known as the Commissioner of Charities. The work of the State Board of Health, he thinks, could be better attended to by one Health Commissioner of the State.

Another Fire in an Insane Asylum.—The Essex County Insane Asylum, at Newark, N. J., caught fire last week, and part of one of the wings was destroyed, the loss being $75,000. The asylum is a new one, and cost $350,000. No blame is attached to the Medical Superintendent, Dr. Hinckley, who acted intelligently and promptly. It is stated, however, that there has been considerable trouble of late about the management of the asylum, and the entire Board of Freeholders are under indictment "for non-feasance in office."

The "American Pasteur Institute."—The certificate of incorporation of the American Pasteur Institute was filed last week in the New York County Clerk's office. The objects of the "institute" are "the gratuitous cure and treatment by the Pasteur system of inoculation, or such variations thereof and improvements thereon as science may develop, of all persons suffering from, or threatened with, or in danger of hydrophobia or any other disease to which the system of inoculation may be found applicable, and the scientific examination of the causes, development, and improved means of prevention of hydrophobia and other diseases through inoculation or kindred methods." The incorporators are Alexander B. Mott, Michael J. B. Messemer, Louis De Pease, Alexander F. Trantard, Charles F. Nirdlinger, Charles Villa, Valentine Mott, and Adolph Corbett. We learn that a company has been organized in St. Louis, Mo., for the purpose of cultivating and using the Pasteur virus against rabies.

The Honor of Knighthood has been bestowed upon Dr. George E. Paget, of Cambridge; Dr. William Roberts, of Manchester; and Dr. James Sawyer, of Birmingham.

Typhus Fever in a Penitentiary.—Within a few days 13 inmates of the Albany Penitentiary have died of typhus fever. There are 1,075 persons in the prison, and one-tenth of them have suffered from the disease in the last six weeks.

The Vital Statistics of the City for the Past Year.—The records of the Health Department show that during the last year there were 35,696 deaths, 30,030 births, and 11,716 marriages, as against, in the preceding year, 35,054 deaths, 30,527 births, and 11,805 marriages. Thus it is revealed that while the death-list increased 662, the number of births fell off 197, a remarkable decrease, due possibly to the sudden cessation of foreign immigration.

Homicides	57
Drowning	183
Total zymotic diseases	9,086

Of the children born 15,534 were males and 14,503 were of the opposite sex; 29,678 children were white and 352 colored; 16,074 were of foreign parentage and 8,107 were of native parentage. The rest were of mixed parentage. The youngest mother and the youngest father were each thirteen years of age. The oldest mother was fifty years of age. Four of the fathers were eighty years of age each. One woman gave birth to triplets and 254 to twins.

The cases of contagious diseases reported during the year were as follows:

Typhoid fever	943	1,101
Diphtheria	2,891	2,221
Measles	4,066	4,392
Cerebro-spinal meningitis	217	228

There were 68,472 vaccinations performed during the year, as against 34,294 during the preceding year.

Medical Society of the State of New York.—The eightieth annual meeting will be held in the Common Council Chamber, City Hall, Albany, Tuesday, Wednesday, and Thursday, February 2, 3, and 4, 1886. The following is the preliminary announcement of papers: 1, Lessons in the Management of Club-Foot, by V. P. Gibney, M.D., New York; 2, Methods of Diagnosis, by Lawson Tait, F.R.C.S., Birmingham, Eng.; 3, Vesical Calculi in Female Children, with Cases, by N. A. Powell, M.D., Edgar, Ont.; 4, Rheumatic Affections of the Joints, by A. Hadden, M.D., New York; 5, Notes of Autopsy Disclosing Absence of the Liver, by Benj. C. Senton, M.D., Whitehall; 6, Peritonitis of Infants and Children, by A. Jacobi, M.D., New York; 7, The Free Dispensary System, by Joseph W. Howe, M.D., New

York; 8, Infant Feeding, by E. F. Brush, M.D., Mt. Vernon; 9, Consultations, by Laurence Johnson, M.D., New York; 10, Medical Testimony and the Hypothetical Question, by Wm. C. Wey, M.D., Elmira; 11, The Recording of Cases; The Effect of the Electric Light upon the Eye, by Lucien Howe, M.D., Buffalo; 12, The Establishment of a State Board of Medical Examiners, by P. R. Furbeck, M.D., Gloversville; 13, Burns Considered as Wounds and Treated According to Scientific and Antiseptic Methods, by Robt. J. Morris, M.D., New York; 14, Antiseptics in Midwifery, by Walter B. Chase, M.D., Brooklyn; 15, The Results of the Operation for Convergent Squint, by D. B. St. John Roosa, M.D., New York; 16, Spontaneous Expulsion of a Large Calculus in the Case of a Female Aged Sixty-eight Years, by Harvey Jewett, M.D., Canandaigua; 17, Leprosy in Japan, by D. B. Simmons, M.D., Poughkeepsie; 18, The Clinical Diagnosis of Cancer Sufficient for Practical Purposes, by Daniel Lewis, M.D., New York; 19, Some Observations on the Treatment of Uterine Displacements in General Practice, by L. E. Felton, M.D., Potsdam; 20, Obstetric Palpation, by W. W. Potter, M.D., Buffalo; 21, Ovarian Tumor—Advantages of Early Ovariotomy, Disadvantages of Delay, by T. H. Squire, M.D., Elmira; 22, Megrim with Intermittent Ptosis, by J. C. Shaw, M.D., Brooklyn; 23, Acute Nephritis, Especially as Following Diphtheria, by A. R. Simmons, M.D., Utica; 24, Treatment of Aural Polypi by the Injection of Carbolic Acid, by Herman Bendell, M.D., Albany; 25, Tinea Tonsurans; or, Ringworm of the Scalp, by F. C. Curtis, M.D., Albany; 26, A Clinical Note on Bright's Disease and Diabetes Mellitus, by Wesley M. Carpenter, M.D., New York; 27, Report of a Case of Empyema, by B. F. Sherman, M.D., Ogdensburg; 28, On the Limitation of the Contagious Period of Syphilis, in Relation to Marriage, etc., by F. N. Otis, M.D., New York; 29, General Arterio-Capillary Fibrosis, its Relation to Cardiac and Renal Disease, by Alfred L. Loomis, M.D., New York; 30, Prevention of Hemiplegia, by W. H. Thomson, M.D., New York; 31, A Case of Tumor of the Maxillary Antrum and Orbit, by T. R. Pooley, M.D., New York; 32, The Early Management of Cases of Mental Depression, by Willis E. Ford, M.D., Utica; 33, A Comparison of Some of the Modern Methods of Treating Ununited Fractures, by Geo. R. Fowler, M.D., Brooklyn; 34, Ulcerative Endocarditis, by H. R. Hopkins, M.D., Buffalo; 35, Cholera, by J. A. S. Grant Bey, M.D., Cairo, Egypt; 36, Fatty Tumors of the Knee-joint, by R. F. Weir, M.D., New York; 37, Treatment of Tertiary Syphilis of the Nose, Mouth, and Throat; Records of Cases Presented and Fully Illustrated, by D. H. Goodwillie, M.D., New York; 38, Ozæna, by John O. Roe, M.D., Rochester, N. Y.; 39. Hygiene of the Ear, Based upon the Record of More than Twenty-eight Hundred Cases, by C. R. Agnew, M.D., New York; 40, History of a Case of Abscess of the Kidney, by C. L. Stiles, M.D., Owego; 41, Remarks on Pelvic Inflammations in Females and Their Treatment, by Arthur M. Jacobus, M.D., New York; 42, (Subject to be announced,) by William S. Ely, M.D., Rochester; 43, Disease of the Fallopian Tubes, with Reports of Cases, and Characteristic Specimens, by W. Gill Wylie, M.D., New York; 44, Report of a Case of Swallowing a Plate with Four Artificial Teeth, the Same being Passed, per Rectum, on the Sixth Day; with Remarks, by L. M. Bates, M.D., Canaan Four Corners; 45, Excision of the Knee-joint, with Cases, by A. M. Phelps, M.D., Chateaugay; 46, Hemorrhage after Removal of the Cervix Uteri for Epithelioma with the Galvano-Cautery Wire, by James P. Boyd, M.D., Albany; 47, The Benefits Arising from Laws Regulating the Practice of Pharmacy, by A. B. Huested, M.D., Albany; 48, Migraine, by Floyd S. Crego, M.D., Buffalo; 49, Cremation, by Charles Cary, M.D., Buffalo; 50, Tubercular Ulceration of the Pharynx, by F. W. Hinkel, M.D., Buffalo.

Communications relating to the above papers, or others that may yet be offered, as to date of reading and time required, should be addressed to any member of the provisional Business Committee: Dr. W. W. Potter, Chairman, 306 Franklin Street, Buffalo; Dr. Daniel Lewis, 62 Park Avenue, New York; or Dr. A. M. Phelps, Chateaugay, N. Y.

A. VANDERVEER, M.D., *President.*
WM. MANLIUS SMITH, M.D., *Secretary.*

ALBANY, N. Y., January 1, 1886.

Reviews and Notices.

AN ATLAS OF CLINICAL MICROSCOPY. By ALEXANDER PEYER, M.D. Translated and Edited by Alfred C. Girard, M.D., Assistant Surgeon U. S. A. First American, from the MS. of the second German edition, with additions. Ninety plates, with one hundred and five illustrations, chromo-lithographs. New York: D. Appleton & Co., 1, 3 and 5 Bond Street. 1885.

THE translator and editor of the book has hereby rendered substantial assistance to his professional brethren in this country, and the publishers have sustained his labor in a most admirable manner. To the microscopist it is encouraging to look upon the beautiful and correct illustrations of what can be seen in the fluids which have been studied.

Illustrations of these structures are so apt to be coarse and misleading that a close approximation to their delicacy in outline will be hailed with intense satisfaction.

Dr. Peyer has divided his subject into nine parts. Dr. Girard tells us that he induced the author to add fifteen new plates. The *first* part is on the microscopical examination of the blood, and the plates illustrate normal and morbid appearances, and also bacilli found in this fluid. The microscopical appearances of milk are illustrated in the *second* part, including colostrum, mastitis, and chronic disease. The *third* part is devoted to examination of the urine, and embraces its general qualities and chemical composition, as well as crystals, casts, epithelium, bacteria, and foreign bodies. Here also we find illustrated the appearances in diseases of the kidneys and bladder, chronic urethritis and spermatorrhœa. The microscopical examination of the sputum makes up the *fourth* part, and we find illustrated the accidental constituents of expectoration, the appearances of the sputum in pulmonary diseases, the tubercle bacilli, Leyden's asthma crystals, the débris of an hepatic abscess which discharges through a communication made with a bronchus, etc. Part *five* contains the microscopy of the stool, with parasites, cholera bacilli, etc. The *sixth* part consists of the microscopy of the contents of the stomach, chronic gastric catarrh, and the echinococcus. Under the head of microscopy of fluid of abdominal tumors, *seventh* part, are illustrated the contents of an ovarian cyst. The secretions of the female sexual organs have been illustrated in part *eight*, and the various micro-organisms provoking disease, such as pyæmia, typhoid fever, pneumonia, and gonorrhœa, are illustrated in part *nine*. The last illustrations are from Friedländer; otherwise the plates are original with the author, and, so far as the reviewer has been able to discover, are more acceptable. The student, the amateur, and the expert will turn to this as a book of reference, and therefore the publishers would have added to its intrinsic value had they given the readers a full index. This defect in a work of this kind is entirely inexcusable, and should be remedied at once.

PHYSICIAN'S VISITING LIST FOR 1886. Philadelphia: P. Blakiston, Son & Co.

THE fact that this is the thirty-fifth year of publication of this handy visiting list is a sufficient indication of its popularity. It contains the usual tables of poisons and their antidotes, doses of drugs, etc.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 9, 1885.

JOHN A. WYETH, M.D., PRESIDENT, IN THE CHAIR.

DR. T. MITCHELL PRUDDEN reported on the specimen presented at the last meeting, in behalf of a candidate, by Dr. H. J. Boldt (see vol. 28, p. 710).

Dr. Prudden also presented, in behalf of a candidate, a specimen of *carcinoma of the stomach, liver, and omentum.*

SARCOMA OF THE LIVER.

DR. H. J. BOLDT presented a specimen removed from the body of a woman, twenty-six years of age, whom he first saw two and a half months ago. At that time she had noticed for the past few weeks a swelling in the right hypochondrium, and that her strength was daily diminishing. On examination he found the entire abdomen occupied, apparently, by an enlarged liver, which extended upward two and a half inches above the nipple, pressing upon the lung and producing bronchial respiration; her heart was also displaced upward. The patient was not very much emaciated. There was an indistinct history of syphilis. The patient was perhaps temperate. Diagnosis of amyloid degeneration of the liver was made, probably due to syphilis. She entered a hospital where the same diagnosis was made, and where, on examination, the spleen was made out to be very much enlarged. She remained in the hospital several weeks, and was discharged, when she again came under Dr. Boldt's observation, and on further examination the history of syphilis became very doubtful, and still further, he ascertained that previously she had had an eye extirpated by Dr. Knapp. He then suspected that the growth in the abdomen was malignant.

Autopsy, twenty-four hours after death. There was complete absence of rigor mortis. The entire abdominal cavity was found occupied by the enlarged liver, the surface of which was smooth, with the exception of one place where a small nodule protruded. The intestines were crowded into the true pelvis, and were firmly adherent to the under surface of the liver. The mesenteric glands were somewhat enlarged. The ascending colon was adherent to the posterior surface of the liver. The spleen was only moderately enlarged. The lungs were compressed. The heart was exceedingly small, but otherwise normal. The liver weighed nineteen pounds six ounces and a half.

DR. J. WEST ROOSEVELT presented specimens of

COMPOUND CYSTIC KIDNEYS

which were interesting, especially in connection with the specimen reported upon by Dr. Prudden. They represented cystic degeneration of the kidneys and liver. They were referred to the Committee on Microscopy.

Joseph C——, thirty-seven years of age, born in Ireland, married, and a laborer, was admitted to Roosevelt Hospital July 6, 1883. He has been a hard drinker, denies syphilis, and has been sick a year or longer, complaining of palpitation of the heart, and muscæ volitantes; first symptoms five or six months ago; dyspnœa on exertion, general anasarca, vomiting, headache, urine passed frequently and was dark in color. These symptoms were severe for a month or more, and then lessened in intensity, the œdema disappearing, the other symptoms remaining. For last three weeks much thirst.

On admission, poorly nourished, flushed face, tongue moist and clean, no œdema, some dyspnœa; pulse, 84; respiration, 21; temperature, 99.4° F.; slight cough and expectoration; urine neutral, 1.003; albumen five per cent., no casts, granular matter. Liver enlarged, abdominal veins enlarged.

July 8th.—Diarrhœa, light-colored stools.

July 12th.—Great dyspnœa in morning, coma at 11 A.M. Death at 3 P.M., with eyes deflected to the right.

Autopsy, July 13th, at 10.30.—Brain: Normal; some thickening of vessels at the base. Heart: Some hypertrophy of the left ventricle; aortic and mitral valves somewhat thickened. Lungs: Adhesions extensive of pleura over right base; some emphysema; both solid with œdema. Liver: Enlarged; filled with numerous cysts, varying in size from being just visible to the size of a lemon. Walls thin; contents of some, thin straw-colored fluid, while others contain thicker dark fluid. Spleen: Normal. Kidneys: Right extends from liver to margin of true pelvis. The colon lies in front of it. The upper end is bent inward as if from the pressure of the liver. Left of same size, extending from diaphragm to near the true pelvis. Both kidneys are converted into masses of cysts similar to those in the liver. These masses retain somewhat the original shape of the kidneys. To the naked eye no normal kidney tissue can be seen, but between the cysts in places are solid yellowish-red masses. Ureters are patent. Renal arteries: Normal. Bladder: Normal. Stomach: Chronic gastritis.

On looking up the literature of the subject, Dr. Roosevelt had been able to find but few cases of cystic kidneys with cystic liver reported. Frerichs, "Syd. Soc.," second edition, p. 223, reports one case. Bristowe, in the "Transactions of the Pathological Society," bound vol. vii., p. 229, and also vol. x., p. 174, reports cases. Murchison, second edition, records a case of supposed simple cyst with rupture. Kidneys not diseased. W. Johnson Smith, "Quain's Dictionary," p. 849, mentions the existence of such cysts and quotes Hulke for dermoid cysts.

CYSTITIS—PYELITIS—ACUTE INTERSTITIAL PURULENT NEPHRITIS.

Dr. Roosevelt also presented a specimen of cystic kidney removed from the body of a patient who was admitted to Roosevelt Hospital eighteen months ago, with acute cystitis and some evidence of pyelitis. Stone was found in the bladder. The patient lived only a few days. At the autopsy there was found an immensely hypertrophied bladder, containing a stone about the size of a walnut. The right kidney contained small cysts without a trace of kidney tissue. The pelvis and ureter were dilated. The left kidney was increased in size, and showed acute interstitial purulent nephritis. The specimen was referred to the Committee on Microscopy.

DR. WACKERHAGEN presented a specimen with the following history:

RESECTION OF THE LOWER FOURTH OF THE FIBULA.

Nellie L——, a school-girl, aged thirteen, native of the United States, in July, 1882, fell on the pavement, producing a contusion on the outer aspect of the right ankle. Aside from the temporary tenderness no lameness resulted, nor was there at any time pain or other sign of inflammatory action, except swelling, until December, when an abscess ruptured spontaneously. A physician was now for the first time consulted. He enlarged the opening, giving free exit for an abundant flow of pus, after which healing was rapid, leaving no apparent injury to the part. A year and a half later, in May, 1884, the first evidence of joint trouble associated with lameness began to develop, the gait became halting, and the ankle swollen, though still without pain or tenderness.

The joint becoming weak the assistance of a cane was necessary—for throwing the weight incautiously upon the crippled foot it inverted, collapsing suddenly. Associated with this tendency to inversion, movements of flexion and extension were more restricted.

Several months now elapsed under somewhat irregular counter-irritative treatment, the trouble meanwhile progressing steadily.

In March, 1885, after prolonged poulticing applied by

the mother, a second abscess ruptured two and a half inches above the external malleolus.

On the 9th of April following, I was called to see the patient, and enlarged the opening by a longitudinal incision down to the bone and on a level with the malleolus. The fibula was found necrotic in its inner anterior diagonal half for a space of an inch and a quarter. The disease had also encroached upon the astragalus, and in scraping away the affected portion the joint was of necessity invaded. A drainage-tube having been inserted through a counter-opening made on the opposite side of the joint, full antiseptic dressings were applied.

There being no improvement by May 13th, excision was determined upon. The periosteum being carefully preserved, two and a half inches of the fibula were removed and the wound dressed antiseptically. Although the wound healed slowly the changes in the deeper structures were quite satisfactory, the bone being renewed and the functions of the joint in part restored.

Return to use of the limb was gradually permitted, with the aid of a crutch, and at the present time the result is almost perfect.

THE PRESIDENT remarked that it was rare to see disease of the fibula and no disease of either the tibia or the joint.

DR. GIBNEY remarked that most surgeons who perform excision of the ankle-joint find the bones of the tarsus so invaded that the result is a rather full gouging of these bones.

THE PRESIDENT remarked that he had performed complete excision of the ankle-joint in six cases within three months, and in no one was the fibula diseased; nor had he ever seen a case in which the fibula alone was affected.

THROMBOSIS OF THE SUPERIOR LONGITUDINAL AND LEFT LATERAL SINUSES—CARDIAC THROMBOSIS—WHITE RENAL INFARCTIONS.

DR. L. EMMETT HOLT presented the heart and kidneys of a female child, seventeen months old, who died in the New York Infant Asylum, November 11, 1885. The facts in the history were furnished by Dr. E. B. Thelberg, the resident physician.

Until six days before death the history of the child presented nothing of importance. It was born in the institution, had been a rather delicate child; dentition had been difficult and accompanied by marked signs of cerebral irritation, generally also by a rise of temperature, once reaching 105° F. These symptoms always disappeared promptly when the teeth pierced the gum. On November 5th an attack, to all appearance similar to those previously observed, began while the child was cutting the canine teeth. Until November 10th there was nothing peculiar about the symptoms. She was exceedingly irritable, tossing about in the crib, or throwing herself violently backward, stuffing the hands into the mouth, and had an irregular febrile movement which ranged from 99° to 103°. The bromides were given in full doses with but slight effect; rubbing the gums with a cocaine solution, which had been found efficient in similar cases, also gave no relief, and only a temporary quiet was produced by three-grain doses of chloral.

On the morning of November 10th the temperature was found to be 104°, and marked cerebral symptoms were present. She was very drowsy, then comatose, the pupils were contracted; no paralysis was noticed. On the following day, about three hours before death, she quite suddenly developed extreme general cyanosis. The pulse at the wrist became imperceptible. Free stimulation by brandy, ammonia, and inhalations of oxygen was employed, but without perceptible benefit. She died cyanotic. There were no convulsions, and no renal symptoms, the urine being passed freely throughout the sickness.

Autopsy, eighteen hours after death.—*Head:* Fontanelle open about three-fourths of an inch wide; dura, normal; pia slightly cloudy, and a little more than normal quantity of the subarachnoid fluid. The *right* hemisphere was intensely congested, the vessels of the pia were turgid and prominent. The *left* side was anæmic, the contrast being very striking. The difference in the vascularity of the two sides existed in the interior of the brain and in the cerebellum. The basilar and main central arteries were examined but showed no obstruction, and no explanation of the condition of the vessels of the cortex referred to.

The sinuses were then laid open, and a firm thrombus was found filling the posterior two-thirds of the superior longitudinal sinus, and the *left* lateral sinus to the jugular foramen. These thrombi were almost decolorized, slightly adherent, and pretty firmly organized. Thrombi were found in several of the larger veins of the cortex of the left side, extending downward from the superior longitudinal sinus. The *right* lateral sinus contained only dark fluid blood.

Thorax.—The lungs were congested and œdematous, but in other respects normal.

The heart was rather pale, but its walls otherwise normal. No signs of endocarditis present. The right auricle was distended, with a firm, pale thrombus very adherent and extending through the tricuspid opening into the ventricle; here it was also adherent. On the left side were similar thrombi in the auricle and ventricle, but smaller than those of the right, being in the auricle the size of the end of the forefinger, in the ventricle about half as large.

Abdomen.—Liver, intestines, and pancreas normal. Spleen about three times the normal size, firm and intensely congested. No infarctions seen. Kidneys slightly enlarged. Over the surface of each fifteen or twenty circumscribed whitish patches seen, varying in size from a small pea to half an inch in diameter. Capsule over these not adherent. On section of the organ they were found to extend into the kidney as wedge-shaped masses, to the depth of from one-fourth to one inch.

Microscopical examination of the kidneys shows the white patches to be areas of coagulative necrosis, with extensive proliferation of new cells at their margins. A number of small capillary hemorrhages were seen scattered through the organ, and some beginning diffuse nephritis.

The condition of hyperæmia of the right side of the brain and the anæmia of the left seems quite an anomalous one, and exactly the opposite of what would be naturally expected. No explanation was found that appeared satisfactory. The appearance of the thrombi themselves, as well as the renal infarctions, showed beyond all reasonable doubt that they were all of ante-mortem occurrence.

It might be well to state that the usual hypostatic congestion of the body externally was equally intense upon both sides, so that the condition of the brain could not have depended upon position.

DR. AMIDON said that if a less careful examiner than Dr. Holt had reported the case he should say that the hemispheres, had become interchanged, but he thought it was not possible in this case. Probably there was some decided obstruction to the arterial circulation of the left hemisphere which brought about, in the first place, the anæmic condition, and in the second place, the sluggish condition in the venous channels which allowed thrombosis to occur. In the absence of examination of the arteries upon that side he should think that was the probable explanation.

DR. HOLT remarked that the large vessels were examined, but not beyond the second bifurcation; and that special care was taken that the hemispheres did not become interchanged, as attention was directed to that point.

DYSPNŒA—ATHEROMATOUS CONDITION OF THE ARTERIES —MULTIPLE CARCINOMA.

DR. VAN SANTVOORD presented specimens removed from the body of a man seventy years of age, an em-

ployee on Randall's Island, who came under observation of the house physician only two days before death, when he was suffering chiefly from intense dyspnœa, with a history of previous shortness of breath. Physical examination showed that he had considerable fluid in both pleural cavities, with a loud cardiac systolic murmur of rather uncertain origin. He died apparently from the effects of dyspnœa.

At the autopsy the brain was anæmic, the arteries were only slightly atheromatous, but were remarkably brittle. There were one or two spots of softening immediately under the cortex. Each pleural cavity contained about a quart of straw-colored fluid, and in the right there were some flocculi of recent lymph. The upper lobes of both lungs showed fibroid phthisis and cheesy nodules. The pleura on the left side was exceedingly thick, both costal and parietal. The upper lobes were firmly adherent to the chest walls.

The left ventricle of the heart was largely hypertrophied. The mitral valves were slightly atheromatous, but there was no insufficiency. The right ride of the heart was substantially normal. The aorta was exceedingly atheromatous, the process having gone so far as to become calcareous. The aortic valves and the coronary arteries were atheromatous, and the processext ended slightly into the large vessels at the root of the neck.

The radial artery was only slightly atheromatous, and exhibited only a slight amount of thickening.

The stomach was eight inches long, and the lesser curvature was occupied by a saddle shaped neoplasm two and a half inches in length and breadth, and about half an inch thick. The mucous membrane did not seem to be involved, and the tumor was apparently situated in the muscular layer. Subsequent microscopical examination showed that it was carcinoma. The liver was about two-thirds the normal size, its capsule was irregularly thickened, and there were some adhesions to the colon and omentum. The spleen was about half the natural size, and its capsule was very much thickened. The mesentery was very much thickened, and by adhesions the colon had been drawn down and presented a remarkable curve. The same process also extended around the rectum. The kidneys were about two-thirds the normal size; the capsules somewhat adherent. The blood-vessels stood out prominently with thickened walls, and they were, therefore, evidently in a condition of marked fibroid degeneration. There was also fibroid degeneration of several of the organs.

The bladder contained a tumor, circular in shape, one inch wide, one-fourth of an inch thick, and presented the same appearance to the naked eye as that found in the stomach. The rectum was adherent to the base of the bladder by an old process, and in its wall was a tumor like that found in the fundus of the bladder.

Dr. Van Santvoord also presented specimens removed from the body of a man who came into Randall's Island Hospital, with the following history:

ACUTE INTERSTITIAL NEPHRITIS—PNEUMONIA—PECULIAR GROUP OF PHYSICAL SIGNS.

On admission his mental condition was fair, and he said he had been sick seventeen or eighteen days with a fever and cough, but without expectoration. There was marked dulness over the upper lobe, with flatness over the lower lobe; auscultation revealed absence of respiratory murmur over the lower lobe, and amphoric breathing over the upper lobe in front. The examination was made by Dr. E. A. Maxwell. On the following day the amphoric breathing had disappeared, and bronchial breathing had taken its place. Over the lower lobe flatness had also disappeared, and bronchial breathing had appeared where there was absence of respiratory murmur before.

The urine contained albumin to the extent of one-eighth of its bulk, and there were epithelial and blood casts, and free blood. This examination also was made by Dr. Maxwell. On the last day of his life the patient had three epileptiform convulsions.

Autopsy.—The body was in a fair state of general nutrition. The brain: The arachnoid was thickened, as if by some chronic process, and under it was a quantity of a somewhat gelatinous lymph infiltrated with pus. This appearance covered the convex surface, and at the base extended into the spinal canal, especially on the posterior surface of the cord.

The upper lobe of the right lung was in a condition of gray hepatization, and differed from that ordinarily observed in the fact that the consolidation extended very nearly to the anterior edge of the lung, which is free, as a rule, in pneumonia of the upper lobe. Dr. Janeway had already called attention to the fact that in pneumonia affecting the upper lobe, and extending nearly or completely to the anterior edge, there might be not only amphoric respiration instead of bronchial, but also cracked-pot note, because the weight of the lung pressed firmly upon the bronchus and gave rise, by pressure, to the possibility of cracked-pot resonance on percussion.

The left ventricle was considerably hypertrophied, and the aorta contained only a trifling amount of atheroma. The radial artery on the right side was exceedingly atheromatous and calcareous, and the process existed to a less extent in the left radial. The vessels at the base of the brain showed only a moderate amount of atheroma. The kidneys contained a few cysts; one cyst at the upper extremity of one kidney was as large as a turkey's egg. The capsules stripped readily, and the kidney itself had considerable fat in the pelvis, and the process appeared to be one of chronic diffuse nephritis with great predominance of parenchymatous change. The urine had shown that there was an acute interstitial nephritis, which was the fatal factor in the case. The other viscera presented no lesions of special importance.

THE PRESIDENT presented specimens of

CONGENITAL TUMORS IN FRONT OF THE ANTI-TRAGUS.

The father had the same kind of tumors, also his sister, and the growths were evidently hereditary. The specimens were referred to the Committee on Microscopy.

TUBERCULAR (?) TESTIS.

The President also presented a specimen of necrosis of the testicle, accompanied with the following history: David D——, fifty-five years of age, married, a native of Holland, and a cutter by occupation, was admitted to Mt. Sinai Hospital December 7, 1885. He had had a hernia on the left side for twenty-five years. About seven months ago his left testicle became enlarged, and was slightly painful. The swelling increased gradually, and was treated, but did not improve. About six weeks ago the swelling began to extend upward into the inguinal canal, and became harder and more tender. The patient had always been more or less constipated. He had had slight abdominal pains, and almost continuous pain just below Poupart's ligament. He had a chill yesterday. He had a perineal abscess two years ago, due to a piece of wood he had swallowed with bread, and which appeared in the abscess. His previous health had been good. He had been treated lately for posterior spinal sclerosis. His family history was negative.

On examination the tumor was as large as a man's fist, and evidently contained fluid. The diagnosis was, possible hydrocele. The symptoms of strangulated hernia were not clear, but it was thought best to cut down upon the mass, with reference to the condition of the testicle, to the possible existence of a hernia, and with a view to removing the fluid. The incision was made, and Dr. Wyeth found a double cyst. The first was outside the cord, and discharged from one to two ounces of fluid; and inside of that was a second cyst which discharged four ounces of serous fluid. There was no hernia. On examining the testicle it was found to be very much en-

larged and nodular—the epididymis as well as the body of the organ. The testicle was removed.

The surgical point of interest was that it could not be determined whether the tumor was a hernia, or an enlarged testicle, or a hydrocele. The specimen was referred to the Committee on Microscopy.

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN PRACTICE.

Stated Meeting, December 15, 1885.

ALFRED L. LOOMIS, M.D., LL.D., CHAIRMAN.

THE PHYSICS OF PNEUMATIC DIFFERENTIATION.

THE discussion was opened by MR. JOSEPH KETCHUM (see p. 31).

DR. E. DARWIN HUDSON, JR., followed in the discussion with remarks which appear on page 29.

Remarks by DR. A. H. SMITH: "It appears to me that the statement by the reader of the paper, that the capacity of the air for retaining moisture is lessened by compression, is opposed to the constant observation that fogs occur chiefly when the barometer is low. So, also, it was observed in the caissons of the Brooklyn Bridge, where the air was always saturated with moisture, that the slightest reduction of the pressure instantly produced an impenetrable mist. The attraction between the molecules of air and the molecules of water is lessened in proportion as they are removed from each other.

"As to the conditions under which the patient breathes when in the cabinet, I cannot see that they differ essentially from those which obtain in the use of the Waldenburg apparatus. In either case there is a difference between the tension of the air inhaled and that of the air surrounding the body; and whether the difference is produced by increasing one or diminishing the other seems to me a matter of indifference. In regard to convenience, however, the cabinet has some advantages.

"As to the gymnastics of the chest, the extra motion is purely passive. It has its value, as passive motion of stiffened joints has, in breaking up adhesions, etc., but it can do little or nothing for the development of the chest-muscles, as no extra activity is demanded of them.

"No comparison can be made between the conditions in the cabinet and those in the caissons of the bridge, since they differ not only in degree, but in kind. In the caissons the pressure of the inspired air and that of the air surrounding the body was the same, and one balanced the other. Had the interior of the lungs communicated with the air outside the caisson, the chest would have been instantly crushed by the unopposed pressure of the compressed air surrounding it. On the other hand, if the pressure had been removed suddenly from the surface of the body, the chest would have been rent asunder by the expansion of the compressed air within it."

DR. PUTNAM-JACOBI had been specially interested in one point to which Mr. Ketchum had directed his particular attention—namely, the importance of condensing the air or vapor, after it has once entered the lungs. She had always understood that in the application of medicated vapors to the lungs the one desirable thing was to avoid their condensation in the upper air-passages before they could reach the lung tissue itself. This difficulty is so great to be overcome that she had been astonished to hear that the inventors of the cabinet had given themselves so much labor and trouble to effect condensation.

In the second place, Mr. Ketchum had shown plainly that inspiration was very much increased; that the lungs could not fail to be expanded; that the air within them was rarefied, and that the divisibility of the vapor was increased; but she failed to see the proof that expiration was increased.

THE CHAIRMAN said that he stood in the position of "a looker-on in Venice," so far as pneumatic differentiation was concerned. It seemed to him, when he was first introduced to it, that the principle was a good one, and on one basis. He did not believe very much in the efficacy of attempts to medicate the lungs by means of spray or vapor, but that in the cabinet, which seemed to him to have a future, was pulmonary gymnastics; and instead of sending patients to high altitudes it may be possible to accomplish, by properly arranged apparatus, what can be obtained by changes in climate. He was willing to assist Mr. Ketchum all that he could in perfecting his instrument, and thought it would not be long before some definite conclusions could be reached, and he also believed that reliable conclusions could be reached only by clinical observations.

DR. W. A. DE WATTEVILLE thought that an important difference between the two methods, that illustrated in the Ketchum cabinet and that applied by Waldenburg's apparatus, was the difference in the influence produced on the circulation. In Waldenburg's apparatus it had been shown that arterial pressure lowered during the respiration of compressed air; while in the differentiation cabinet arterial pressure rose. He thought that this important difference in the physiological effects produced on the circulation showed that there was a difference between inhaling compressed air and inhaling air at ordinary pressure while the body was in a vacuum.

DR. PUTNAM-JACOBI had taken sphygmographic tracings, both before and after the inhalation of compressed air, and had found that the arterial pressure on the radial pulse was increased by the use of the Waldenburg apparatus.

MR. KETCHUM, in closing the discussion, said that Dr. Smith in his remarks had ignored the element of temperature and the question of dew-point.

With reference to the amount of total air during respiration, referred to by Dr. Putnam-Jacobi, he thought it was distinctly stated in his paper that while the initial inspirations ranged from twenty-eight to forty cubic inches, the succeeding inspirations were of no greater amplitude than normal, except that which was due to increased muscular effort, which would vary with different individuals. The expiratory effort was more forcible, as indicated by the manometric test, and it was so for several reasons, which time did not permit him to give.

The amount of condensation would vary with the specific gravity of the fluid and the amount of pressure employed.

The Section then adjourned.

ARTIFICIAL HIBERNATION.—Professor Gruselbache, of the University of Upsala, if the account be true, has evidently been studying "The Man with the Broken Ear," for he proposes to freeze somebody and keep him for two or three years in this glacial condition. He advertises for some obliging individual who will submit himself to the experiment, and promises to thaw him out, well in body and mind, whenever his friends desire. If he cannot find a volunteer he asks the Government to give him a condemned criminal. This would be an excellent plan for governments with large standing armies to adopt; they could keep their soldiers on ice at a slight expense, and then could thaw them out whenever war was declared. There are also numerous other directions in which this method could be applied, and it offers a solution for many perplexing problems of our age. Long live Professor Gruselbache—on ice.

THE RUDOLPH-STIFTUNG IN VIENNA.—The report of this hospital for 1884 shows a total of 8,042 patients treated during the year. Of this number, 4,677 were discharged cured, 1,377 improved, and 413 unimproved. The deaths numbered 894, and 681 remained in hospital on January 1, 1885.

Correspondence.

OUR LONDON LETTER.

[From our Special Correspondent.]

THE COLLEGE OF SURGEONS—CONVOCATION OF THE UNIVERSITY OF LONDON—PROFESSOR JOHN WOOD ON ANTISEPTICS—DISEASES OF THE CIRCULATORY ORGANS IN ANIMALS—FRESH TITULAR DISTINCTION FOR THE MEDICAL PROFESSION.

LONDON, December [illegible], 1885.

ANOTHER meeting of the fellows and members took place at the College of Surgeons the day before yesterday. The resolution proposed by Mr. Timothy Holmes, Surgeon to St. George's Hospital, London, and seconded by Mr. Sampson Gamgee, of Birmingham, was carried by a large majority. This was expected, but there was some opposition, led by no less a personage than Mr. Brudenell Carter, who, to his other qualifications, adds that of a good speaker. The resolution which has been carried is the following: "That the answer of the Council is, in the opinion of the meeting, not satisfactory, and that the Council be respectfully requested to reconsider the questions—firstly, of the representation of members; and, secondly, of submitting for approval any alterations proposed to be made in the constitution, or in the relations of the College, or in any of its by-laws, to a meeting of the fellows and members." The Council of the College has shown itself such a conservative body that it is not much more likely to take any real notice of this resolution than it did of those carried at former meetings of the members and fellows in conclave assembled.

Meanwhile, it may be remarked that the College Council is not the only body opposed to change when affecting itself. The Convocation of the University of London, at its last meeting, showed pretty plainly that it wished to have nothing to do with the movement for promoting a teaching university or to institute any reforms in the existing university. At its last meeting it virtually stultified its previous action. One of the speakers (Dr. Broadbent, Examiner in Medicine), in moving the adjournment of the debate, remarked that his motion, if carried, would lead to the matter being dropped and nothing more being done, and even went so far as to say that this was most desirable. His co-examiner in medicine, Dr. Ord, is in favor of the new movement, though he did not speak at this meeting.

Professor John Wood, in his recent Bradshawe lecture, took up the subject of antiseptics. He is an earnest advocate for their use, and employed them in his wards at King's College Hospital before the advent of Lister to London. We are now so accustomed to the use of antiseptics in surgery that it seems impossible that their introduction can have been so recent. Professor Wood, however, and many of us who are even younger than he is, can remember the pre-antiseptic era. To go back to the time when, although known, antiseptics were far from being universally adopted needs no great effort of memory. Antiseptics have only been generally adopted in British surgical practice within the last ten—or, at most, fifteen—years. Their application to obstetrics is still more recent. Concurrent with the more general use of antiseptics has been the increased attention generally paid to hygienic measures. The importance of the latter as a factor in influencing the satisfactory progress and healing of wounds did not escape Mr. Wood in his recent discourse on the subject. "It is," he said, "in very great measure owing to the remarkable advance in this particular that so much improvement has taken place in longevity, in the rate of mortality, in the shorter duration of surgical complaints, and in the less fatal results of surgical operations during the last twenty years."

Hygienic precautions, strict cleanliness, and the proper application of drainage are placed by Mr. Wood in the fore-front of the precautions to be adopted by the surgeon. Coming to the use of appliances more strictly denominated antiseptic, the lecturer referred to the gradual abandonment by most surgeons of the spray and the gauze dressings, in which he was inclined to concur. Corrosive sublimate was favorably spoken of, but it was suggested that we need further experience to confirm its value. Mr. Wood then referred to some experiments he had lately been making with peroxide of hydrogen as an antiseptic. He employed it in aqueous solution. It was very active, and absolutely non-irritating. Its weak point was its instability. One part in two thousand prevented putrefactive fermentation and destroyed the activity of bacteria and micrococci. It was very convenient in its application. A piece of absorbent cotton was dipped into the solution, squeezed over the wound as a wash, and then laid upon it as a dressing. Over this a piece of thin gutta-percha tissue or oil-skin was laid, and covered with a layer of absorbent or salicylated cotton wool, and bandaged lightly. In deep sinuses and irregular wounds it might be used with a syringe or irritating apparatus and double tubes.

Comparative pathology at present possesses a most able worker in the person of Mr. J. Bland Sutton, of the Middlesex Hospital. Mr. Sutton's labors are unremitting. At the last meeting of the Pathological Society he read a paper on "Diseases of the Circulatory Organs in Animals." He has found lesions of the heart and vessels to be by no means of so frequent occurrence as in man. Pericarditis arose from the same causes, and was very similar to the same disease occurring in man. Galen, he remarked, described the first case of pericardial effusion, and it occurred in a monkey. The milk-white patch was frequent in some birds and monkeys as a consequence of pressure from rickets. Rickety deformities also led (through the pressure they caused) to a very serious condition of the heart, which might be denominated "flexion." Affections of the valves occurred occasionally, leading to incompetence and its results. Diseases of the vessels were very rare, especially atheroma. Arteriocapillary fibrosis affected the medium-sized arteries in horses and cattle, and was associated with chronic interstitial nephritis, as in man.

Amid the kaleidoscopic political changes going on around us, it is with some surprise that I have just seen the announcement of two fresh titular distinctions for the medical profession. Dr. G. E. Paget, of Cambridge, is to have a K.C.B. bestowed on him, and Dr. William Roberts, of Manchester, is to be knighted. Dr. Paget is Regius Professor of Physic in the University of Cambridge, and a brother of Sir James Paget, the eminent London surgeon. Dr. William Roberts is Professor of Clinical Medicine in the Victoria University. In neither case can the title of "Sir" enhance the distinguished professional reputation already enjoyed by each of these gentlemen.

OUR PARIS LETTER.

[illegible]

ACCIDENT FOLLOWING ANÆSTHESIA BY PURE PROTOXIDE OF NITROGEN IN FRANCE AND PRECAUTIONARY MEASURES REGARDING THE SAME—THE ADVANTAGES OF THE ADMINISTRATION WITHIN THE LIMITS OF SOME [illegible] NEW PURGATIVES.

[illegible]

AT a recent meeting of the Société de Biologie, M. Grehant read a paper for M. Lafont on the accidents following anæsthesia by pure nitrous oxide, or laughing-gas. It is known that this agent produces anæsthesia only by causing a veritable asphyxia, and that its employment is often followed by very grave accidents. Among the consecutive accidents observed by M. Lafont may be mentioned: 1. The death of a fœtus in a young woman enceinte five months, in whom anæsthesia was employed for the extraction of a tooth. The movements of the child ceased on the very day of the

anæsthesia, and the expulsion of the dead fœtus took place a month and a half after. 2. The appearance of albuminuria in a certain number of patients suffering from cardiac disease. 3. The suppression of the menses in a young girl who had just reached puberty. 4. The recurrence of epileptic fits in a young man who, after several years, had had no attack. Other cases occurred, but which need not be entered into here. M. Lafont, however, observes that there are numerous contra-indications against the employment of pure laughing-gas, and he thinks it advisable to give it up altogether in practice.

This note reminds me of a case that was lately tried at the Correctional Tribunal of Paris, at which a dentist, M. Duchesne, was condemned to pay three thousand francs damages and a fine of six hundred francs for having administered laughing-gas to a patient who went to him for the extraction of a tooth, and who, after a few inhalations, fell into a state of syncope and died. The dentist not being a qualified man must think himself lucky that he got off so easily; but what saved him was that Dr. Brouardel, the medical jurist, declared that he could not affirm that the death of the patient was caused by the anæsthesia. All he could say was, that the patient's blood contained a certain quantity of nitrous oxide, but that the fatty condition of the heart had a great deal to do with the accident.

Rabies, which, during the period from 1880 to 1884, diminished in Paris in a notable manner, had become more prevalent at the end of last year, and has continued with scarcely any abatement to the present time. From the commencement of the present year twenty cases of death from the disease have already been registered in Paris, and this figure is the highest that has as yet been attained. In consequence of the alarming increase of such a terrible malady, M. Leblanc proposed, at the meeting of the Academy of Medicine, last week, that the following measures should be carried out: 1. That the law of July 21, 1881, which prescribed the declaration of all cases of hydrophobia, the destruction of all animals bitten, the wearing by dogs of a collar of a certain kind, and the taking to the pound those that are found straying. 2. To render general and uniform the organization of the service of epizootics, and to place this service under the direction of veterinarians. 3. To cancel the adjournment of the article of the law forbidding empirics to treat animals affected with contagious maladies. To these propositions, which were unanimously accepted by the Academy, M. Le Fort added another compelling owners of dogs to attach to the collar a small medal bearing a mark showing that the tax had been paid for the year. All dogs not wearing these articles will be treated as stray dogs. M. Dujardin-Beaumetz, in supporting the conclusions of M. Leblanc's report, pointed out the difficulties in carrying out these regulations. M. Dujardin-Beaumetz has been charged for the last five years to search for cases of rabies among the population of Paris. In his report he observed that, as the spontaneousness of rabies is universally denied, the governing bodies are bound to enforce such police regulations as may be necessary to prevent the spread of the disease. It would appear that these regulations are strictly enforced in Germany, where hydrophobia is by no means so common as it is in this country, and even in Great Britain. According to M. Dujardin-Beaumetz's report, there were in Paris, in 1881, 17 cases of death from hydrophobia; in 1882, thanks to the measures that had been taken, there were 11, and in 1883 there were only 6. In 1884 no case of the disease occurred in the first half-year; in the second half 3 cases were reported. In 1885, 20 cases have been registered to the present date.

Since the above communication by Dr. Dujardin-Beaumetz, this physician made another report to the Council of Hygiene of the Seine, to the effect that a case of death from hydrophobia recently occurred at the Hôtel Dieu, and that he had reason to believe that the disease came on spontaneously, as the body bore no marks of having been bitten. The patient was, however, epileptic, and this circumstance would tend to infirm Dr. Dujardin-Beaumetz's conclusion, though the patient denied having ever been bitten. Nevertheless, experiments performed by M. Pasteur on two rabbits which he inoculated with fragments of the medulla oblongata of the patient proved that the latter died from hydrophobia.

At a recent meeting of the Academy of Medicine, Professor Vulpian read a paper on the advantages of the salicylate of lithin in the treatment of rheumatism, whether it be acute, subacute, or chronic. He has found it most useful in cases where the salicylates of soda and quinine failed to effect a cure. Moreover, the inconveniences caused by these drugs are scarcely perceptible in the administration of the salicylate of lithin. It is given in large doses, the same as is done with the salicylate of soda.

At the same meeting, Dr. Desnos, candidate for the membership of the Academy in the section of therapeutics, read a paper on the action of some of the new purgatives brought to notice by Professor Rutherford, of Edinburgh; but while the latter physician experimented on animals, Dr. Desnos submitted the new drugs to clinical experiment. These are sanguinarin, bactisin, juglandin, and phytolaxin. These substances are resinous, and are employed in doses varying from 10 to 60 centigrammes. The effects of the first are nearly *nil*, those of the other two are more certain, while the phytolaxin, in particular, is considered a great acquisition to therapeutics.

CONCERNING THE DISINFECTION OF RAGS.

To the Editor of The Medical Record.

Sir: Mr. Augustine Smith, in his letter anent the disinfection of rags, published in your issue of this date, makes several statements reflecting upon his namesake, the Health Officer of the Port, which, in the interests of justice and of public health, require correction. His first complaint, that rags are to be disinfected "to the satisfaction" of the Health Officer, rather than to that of the importers, would scarcely seem to a professional mind to involve such very improperly "arbitrary power," even if it were strictly in accordance with fact, forasmuch as the said Health Officer is held responsible for the satisfactory exclusion of infection; but, in reality, the rules adopted by Dr. Smith are those which were unanimously formulated by a conference of sanitarians, held at the request of Dr. Smith himself, in his reluctance to exercise his undoubted authority in any way which might seem to inflict hardship upon the rag importers without the concurrence of other representatives of preventive medicine, and of the quarantine establishments of different ports. No one at that conference supposed that the manufacturers of paper "wish to import disease" any more than the opponents of vaccination wish to diffuse small-pox; but it did not occur to them that these manufacturers of paper were the best and most unbiased judges as to either the desirability of disinfection or the most efficient process of performing it. Furthermore, whatsoever may be Mr. Smith's doubts or opinions on the subject, statistics show that there is danger of the importation of infectious disease by rags, and experiment demonstrates the possibility of "thorough disinfection," even in the bale, and it is hardly consonant with the principles of sanitary administration to wait until a suspected article "can be shown to be infected" before taking precautions to render it innocuous. The circumstance that rags may be shipped from a port free from epidemic disease is no evidence that they have not been gathered from infected districts, as every one familiar with the practices of the ubiquitous nomadic "chiffonier" must be aware; and if the public insisted on the importance of promiscuous disinfection of the mails from Canada last summer, it is not likely that this same public will regard as an "out-

rage" any measures to guard against the risk of infection from rags which may, even by remote possibility, have been cast out, soiled, from a sick room or a hospital ward.

Mr. Smith omits to state that the methods of disinfection recommended were to apply to rags which had not been disinfected before exportation, and that several processes were mentioned which should be regarded as "satisfactory" if done abroad, and certified by a responsible person to have been done.

It was, in the opinion of every one present at the above-mentioned conference, to be regretted that what had been shown to be an effective apparatus for the disinfection of baled rags was covered by a patent; and it is still to be regretted that where the safety of the whole community is concerned the Government cannot either purchase the patent or defray the cost of protecting the public health in this as in other respects; but Mr. Smith's allusion to an imaginary "quarantine ring," which by implication must embrace the health authorities of other ports, as well as a number of representative sanitarians in different parts of the country, is as absurd as it is spiteful.

I am, Sir, yours, etc.,

ALFRED LUDLOW CARROLL, M.D.

New Brighton, [illegible]

THE EARLY USE OF IRON IN DIPHTHERIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Dr. Winter's article on diphtheria, in your last issue, is a notable exception to the all-pathological, all-etiological style of most of the great writers who spare the time to write for medical periodicals, and I for one thank him for it. He mentions Dr. Heslop, of England, as the first to recommend the iron treatment in this particular disease, and also alludes to the immense doses given by different observers. Dr. C. D. Parke, of this city, is perhaps the first physician on this continent who demonstrated the virtue of this treatment, and his success was so great from the first, that to this day he is called the diphtheria doctor by the public, who are always quick to appreciate and reward success. He began his treatment about the same time (1858 and 1859) that Dr. Winters credits Dr. Heslop with having introduced it in England, wholly independent of any previous knowledge of its use. His observations led him to consider diphtheria allied in nature to erysipelas, which was prevailing also about that time. His success has been remarkable: from that day to this, nearly thirty years, during which time he has been engaged in active practice, he has only lost one case—one which obstinately refused all medicine—and has treated, perhaps, more cases than any physician in this section of the country. Strange to relate, he lost a child of his own with this disease, under the treatment of other physicians, to whose care he consigned it; but this case was one of laryngeal diphtheria. He has had no cases of laryngeal diphtheria in his own practice, which he attributes to the early and rapid use of iron—tincture of iron (which he has used in this disease for nearly thirty years), in large and hourly doses, ten to forty drops, with equal quantity of chlorate of potassa in syrup of acacia and water, or glycerine and water. He does not term primary cases of pseudo-membranous croup as diphtheria, nor has he had to treat any such cases. That we have diphtheria here, in severe types, too, there is no sort of doubt, as the sequels show. I have to-day a patient who has been convalescent from this disease for more than a month, who speaks with great effort, from paresis of the soft palate; who cannot see the figures on the clock-dial, and whose heart beats so feebly that he has fainted four times in the past month from too great fatigue in sitting up, contrary to my orders. I have seen in the past five years three deaths from cardiac paralysis, due to ignorance or neglect in the matter of convalescence in this disease. I have written you this letter for what it is worth, and I think all such data are worth something. That the physicians of this city are more than ordinarily successful in the treatment of this disease I am firmly convinced, both from ample experience in the observation of its ravages North and South, and also from written reports. Dr. F. M. Peterson, of Greensboro', in this State, also independently worked out this treatment, and has been eminently successful in his practice. Dr. Parke, and the remainder of us following in his lead, give calomel at first as a purge, then iron every hour—in bad cases, night and day—followed at once by a drink of rich, sweet milk; and if the membrane do not extend to the larynx, and the patient do not get up too soon, they get well; no matter how bad matters look, they get well. I have seen the pulse in children drop to fifty-eight beats to the minute, and stay there for days and days, and yet get well.

Strange to tell, and unjust to himself, Dr. Parke seldom, if ever, writes for publication; he does not bother his brains much about bacteriology, but he certainly knows how to cure diphtheria.

If this is worth the space, please do justice to this worthy and useful man, who still works in the harness at a ripe and honored old age. Very truly yours,

F. TIPTON, M.D.

HINTS ON THE TREATMENT OF PERSISTENT CONSTIPATION.—*The Lancet* publishes the following letters from various correspondents giving suggestions for the treatment of constipation:

SIR: In reply to your correspondent, "Physician," who asks in your last issue for some hints on the treatment of persistent constipation, I beg to suggest a plan which I found entirely successful in a case which I had recently under my care. The patient, a young man aged twenty-three, had suffered for six months from most obstinate constipation, for which he had tried numerous remedies, but without relief. At the time he came under my care he usually only had a motion, and that a scanty one, once in every week or ten days. I ordered ext. cascaræ sagr. liq., ʒj.; tr. nucis vom., ɱlx.; tr. belladonnæ, ɱv.; to be taken in water every night and morning; the abdomen to be rubbed firmly from right to

left for ten minutes every morning, and the diet to consist largely of porridge, brown bread, and stewed fruit, with entire abstinence from tea. Four hours after the second dose of medicine had been taken he passed a most copious motion. At the end of a week, as the bowels had acted each day, the dose was reduced to half, and continued for another fortnight, by which time he was quite cured. T. L. KENRICK DAVIES, M.B.

SIR: In answer to "Physician," I write to say that I have found the following prescription most successful in some cases of the above complaint: ℞. Tr. nuc. vomic., ♏100; tr. calumb., ʒ iv.; ammon. carb., ʒ ss.; sp. chlorf., ʒ iss.; dec. aloes co., ℥ j.; aq. camph. ad ℥ viij.: an eighth part to be taken two or three times a day, the first dose being taken each day about an hour before breakfast. I am aware that your correspondent says he has already tried strychnine, but possibly he may not have done so in the above combination.

W. L'HEUREUX BLENKARNE.

SIR: Let "Physician" administer to his patient every night, or, if necessary, night and morning, a pill containing one-sixth of a grain of extract of belladonna and half a grain of sulphate of zinc. I feel sure he will be more than satisfied with the result. ARCHD. HAMILTON.

SIR: I would recommend "Physician" to try either one-grain pills of pil. aloes glacialis or the mist. cascara sagrada comp. in teaspoonful doses. Both can be repeated at frequent intervals.

J. G. BRADEN, M.R.C.S.

SIR: If "Physician" will give ʒ ij. ol. ricini, ʒ ij. glycerinæ, and ʒ ss. q. ext. cascara (Battley & Watts) every night at bedtime, he will find the action all he could desire. LARD.

THE PROPORTION OF SURGICAL OPERATIONS THAT ARE NECESSARY.—Of one hundred possible operations, twenty are imperatively necessary, twenty are absolutely inadmissible, and the remaining sixty may be performed or not according to circumstances; and surgeons may and do err in each of these classes of cases.—PROF. VERNEUIL.

WHEN SPECTACLES SHOULD BE USED.—When we are compelled to remove small objects a considerable distance from the eye. When we find the light insufficient. When the object appears blurred, cloudy, or has a mist before it. When the letters of a book run together or appear double or treble. When the eyes become fatigued after reading or other exercise. These rules answer in many cases, but not always. Never choose a pair of spectacles when the eye is fatigued. Wait an hour or two, after you can be better suited. The tired eye needs rest, not glasses, and if they are purchased when the eye is excited or tired, errors are certain to occur in selecting the proper glasses. Wait patiently for an hour or two, or better still, three.—*The Medical Summary.*

POP-CORN AS AN ARTICLE OF DIET.—It is said that chemical analysis of pop-corn shows it to contain more albuminoids than most of the other cereals, and in certain parts of the West it is extensively used as a regular article of food. Our Pilgrim Fathers made some personal experiments with pop-corn, the result being that they started a Day of Thanksgiving for not having to live on it any longer.

A SURE CURE FOR HYDROPHOBIA.—An enterprising physician has secured for himself a thirty days' advertisement on the editorial page of *The Sun* in exchange for the following remedy, which he asserts cured one terrible case of hydrophobia: ℞. Potass. iodid., ʒ iij.; tinct. cinchonæ, ℥ ij.; syr. simplicis, ℥ iv. Sig.: A tablespoonful after each meal for an adult; for children, from one-half to two teaspoonfuls. He takes the wise precaution, however, to cauterize the wound with nitric acid. He does not say whether the simple syrup or the cinchona is the active agent.

WHAT THE PROFESSION NEEDS.—"A full one-half of the young men who come to Philadelphia to study medicine should be turned face about and sent to a village school. The place to intercept incompetents is at the entrance of the medical schools, rather than at their exit."—*Dr. J. E. Garretson.* "The profession is now thoroughly awakened to the necessity of arresting the course of the schools that are annually sending forth thousands of improper persons to practise on the community. . . . The diploma of schools should be beyond suspicion. The signatures should do more than convey the mere intelligence that the holder of a certain certificate has paid his money for two courses of lectures and thirty dollars for the engrossed parchment attesting the same. It does little more just now."—*New England Medical Monthly.*

A SIMPLE EVAPORATOR.—Dr. Cheize, in the *Glasgow Medical Journal*, writes that, wishing to remove an ingrowing toe-nail, and being without a spray-producer, he covered the toe with a pledget of the size of a crown-piece, poured ether on it, and evaporated this by means of a pair of bellows; in five minutes anæsthesia was complete, and lasted while the nail was removed and the matrix seared with the actual cautery.

IODOL—A SUBSTITUTE FOR IODOFORM.—To the progress of synthetical chemistry we owe an addition to our present list of local antiseptics which, if on further trial it be found to bear out the promises made for it by its discoverers, bids fair to take the place of iodoform altogether. Iodol, the substance referred to, is a dark powder obtained from "Dippel's animal oil." It has but little smell, and is soluble in three parts of absolute alcohol, but only in 5,000 parts of water. More than two hundred observations on various diseases have been made with it in the Royal Surgical Institute in Rome. It was used in substance, suspended in glycerine, dissolved in alcohol with glycerine, and as ointment. Chancres were washed with distilled water, very carefully dried, and sprinkled with iodol in powder, and covered with silk protective, the dressing being changed daily. In six days' time the base of the chancres began to granulate, and the edges to show signs of commencing cicatrization. Similar treatment was adopted in the case of open buboes, which very soon began to exhibit a healthy appearance, and in a short time healed up. In many cases of simple indolent ulcers iodol was equally valuable, the whole character of the sore becoming changed after a few applications. Neither erysipelas nor diphtheritis was ever observed in cases treated with iodol.

POST-MORTEM MUSCULAR MOVEMENTS.—At a recent meeting of the Biological Society of Paris, M. Brown-Séquard related some experiments he had made, by means of a special instrument, to determine the movements of single muscles in the body after death. He had found that there was a very considerable degree of contraction and relaxation, as much, for example, as 2½ mm. in a muscle measuring only six millimetres in length. He thought that the results of his experiments disproved the theory of coagulation in the muscular tissue as the cause of cadaveric rigidity.

THE DRY TONGUE IN FEVER.—Dr. Cotter writes in the *Indian Medical Gazette*, that he has had great satisfaction with the use of glycerine painted over the tongue in fevers. It keeps the organ moist and removes the sensation of great thirst and discomfort caused by a dry and foul tongue.

THE ACTION OF HOT BATHS.—Dr. Livierato states that the temperature of the body may be raised from 3° to 5.5° F. by immersion in a hot bath. This elevation may be maintained for nearly an hour if the patient be wrapped in blankets. Not only is the body-heat raised, but the amount of urea excreted in the twenty-four hours may be increased as much as 90 grains above the normal.

ON THE RELATION OF LITHÆMIA, OXALURIA, AND PHOSPHATURIA TO NERVOUS SYMPTOMS.[1]

With a Description of an Apparatus for Estimating the Relative Amounts of Phosphatic Deposits and of Uric Acid in the Urine.

By C. L. DANA, M.D.,

[illegible] Diseases, New [illegible]

EVERY one must feel that it is very desirable, in certain chronic functional nervous disorders known clinically as nervous asthenia, hypochondriasis, spinal irritation, etc., to get hold of something objective, some actual evidence of diseased action. In these conditions we have generally to rely upon the patient's statements, and to base our diagnoses on a clinical picture as set forth by a highly awakened imagination. We need something more tangible than this, and physicians have, therefore, turned to the kidneys as likely to furnish a more definite secretion to work upon than does the cerebrum. The results have been to find that with these symptoms of nerve irritability and exhaustion there is often some peculiar condition of the urinary secretion. The terms applied to these conditions are glycosuria, oxaluria, phosphaturia, and lithæmia. There has also been observed, in very rare instances, an excessive excretion of urea, which is called azoturia.

For some time I have been studying the subject of the relation between these urinary disturbances and nervous symptoms. I have tabulated notes of one hundred and ten cases, in most of which the condition of the urine was examined, and in thirty-one of which careful analyses to determine the amounts of uric acid, oxalic acid, phosphates, and sugar were made.

In order to support what conclusions I have been able to make, I shall have first to discuss briefly the urinary disorders referred to.

Oxaluria is a term first given by Dr. Prout to indicate an excessive discharge of oxalic acid in the urine. Dr. Prout, and later, Dr. Golding-Bird, held that there was a true oxalic-acid diathesis. It was characterized by flatulent dyspepsia, melancholia, and nervous irritability and depression. The views of these physicians have been denied by later observers, including Drs. Owen Rees, Beneke, Seligsohn, Bence Jones, and Dickenson. Of late, however, the older view has been revived by Professor A. Cantani, of Naples, who claims that there is not only an oxaluria but an oxalhæmia.

The facts seem to be that oxalic acid, in the form of oxalate of lime, is frequently excreted in normal urine. According to Schultzen it is excreted to the amount of 0.07 gm. daily. A pathological increase occurs in conditions of increased acidity favoring the deposition of urates, and in these cases some of the oxalic acid is formed from the urates. *Oxaluria is oftenest only an indication of lithiasis.* It is also found, however, whenever earthy salts are excreted in excess, and Dickenson thinks that its presence indicates an excessive loss of earthy salts. It [illegible] appears to me that we can discard the term oxaluria altogether, for when oxalate is found continuously in excess in the urine, careful examination will show either an over-acid urine and urates, or sugar; while, on the other hand, when earthy salts are passed in large amount, and some oxalates are formed, they have of themselves no significance (Dickenson). At the same time there are, perhaps, occasional cases of true oxaluria. Thus Furbinger (*Deut. Arch. f. Klin. Med.*, Bd. xvi., p. 500) reports a case in which there was alternately glycosuria and oxaluria. Others have at times reported cases in which there was simply an excess of the oxalate without any excess of urates or phosphates, and without sugar (Dr. C. N. Durselen, *Cin. Lancet and Clinic*, 1884, p. 683). The positive views of Cantani as to the existence of an oxaluria, appear to be not well substantiated. I have not seen his original work, but from a digest of it by Seligsohn ("Eulenberg's Real-Encycl.," Article "Oxaluria") it would appear that his assertion as to an excess of oxalate of lime in the blood was based on a single examination, and that his cases of oxaluria were really cases of lithæmia, or of excessive loss of earthy salts. I have not met with any case which I could positively speak of as one of oxaluria.

The relation of lithæmia to nervous symptoms is a most interesting one. Many writers, from Aretæus down, have called attention to the gouty nature of various severe nervous symptoms, more especially, perhaps, of those of hysteria (Whyth, Laycock), hypochondriasis (Handfield Jones), and neuralgia; and Laycock in particular ("Nervous Diseases of Women," pp. 165, 166) seems to aim to show that hysteria in woman is much the same thing as gout in man. Trousseau refers to the relations between gout and hysteria. Indeed, a long list of authors could be cited who have dwelt upon the relations between the gouty dyscrasia and nervous diseases (*vide* Laycock, *loc. cit.*). With the decline of the humoral pathology the importance of these dyscrasiæ, or toxic conditions of the blood from defective metabolism, was somewhat lost sight of. In 1881 Dr. Da Costa (*American Journal of the Medical Sciences*, October, 1881) called attention to certain clinical facts bearing on this subject. These were, that persons of a lithæmic tendency and history, persons who had a latent gouty disposition, occasionally passing urates in excess, might suffer from a long train of distressing nervous symptoms, such as objective vertigo, periodical headaches, neuralgias, cramps in the legs and muscular twitchings, pains in the fingers, parasthesia, insomnia, great nervous irritability, lassitude, melancholia, and even hysteria. Dr. Da Costa ascribes these symptoms to the irritant action of the over-acid blood, and called the disorder not "American neurasthenia," but "American gout." I am not aware that subsequent writers have brought forward any distinct evidence in support of these views, but they have, I believe, been quite widely received and adopted.

I have myself made many examinations in order to corroborate them, if possible. In about one-fifth of those cases, showing exaggerated nerve-irritability, I have found some evidence of over-acid urine, with excess of urates, and in the majority of these have caused great benefit by the adoption of anti-lithic treatment. Sometimes, even when the urine was cloudy and feebly acid, I have found that there was in reality a small amount of phosphates and an excess of urates.

[1] Read at a meeting of the Practitioners' Society of New York, December, 1885.

I have a striking illustration of this. A married woman, fifty years of age, came to me complaining of great nervousness, confusion of mind, irritability, and depression. She had no organic disease anywhere. Her father died insane, her mother was rheumatic. Of seven brothers and sisters nearly all were rheumatic, but had no nervous troubles. She herself had never had acute rheumatism, but at the time of her visit she had some muscular pains. Her urine was cloudy with phosphates, neutral. On precipitation with Teissier's solution, I found the phosphates below the normal, the urates on the first test acid, sp. gr. 1.022, with an excess of phosphates and a slight excess of urates. Under bicarbonate of potassium his symptoms improved remarkably.

In none of my cases have I been able to get the slightest evidence of developed gout. The histories were sometimes those of rheumatism, either personal or hereditary. In other cases no well-marked gouty or rheumatic history was obtained, and yet there was at times excess of urates.

So far as my experience goes, I cannot see on what ground the term gout is used in connection with these

ILLUSTRATIVE CASES.

	Patient.	Symptoms.	Condition of Urine.	Treatment.	Result.
1	Mrs. H——, aged thirty-two.	For a year has had gastric distress from dyspepsia; constipation; vertigo; headaches and neuralgic pains; morbid fears and very great nervousness; has had one hysteroid convulsion; lacerated cervix.	Urine evening and morning, 1.030, cloudy, acid; urates in great excess, phosphates normal or below average (three examinations).	Diabetic diet. Powders of pepsin, soda, and capsicum; pil. hydrarg. twice weekly.	Great improvement; subsequent relapse, followed by improvement under potas. bicarb.
2	Mrs. M——, aged thirty-eight.	Several years ago had "oxaluria," now has great nervousness, irritability, and mental depression; flatulent dyspepsia of severe type; constipation; epigastric distress; vertigo; periodical headaches; insomnia; chronic bronchitis.	Urine cloudy, acid; excess of urates.	All forms of medicine, such as acids, alkalies, bitters, made her worse; under a meat and milk diet, six light meals daily,	She improved vastly, and wrote me she felt very well.
3	Mrs. W——, aged thirty.	Has been extremely nervous; has morbid fears, vertigo, headaches; a moderate degree of dyspepsia.	Urine dark, acid, 1.028; urates in excess, phosphates average.	Meat and milk and green vegetables; pil. hydrarg. twice weekly, potas. et ferri tart.	Very great and immediate improvement.
4	Mrs. A——, aged twenty-eight.	Very nervous; left intercostal neuralgia; palpitations; slight dyspepsia.	Urine light, cloudy, acid, 1.018; no sugar or albumin; phosphates below average, urates very excessive.	Nitrogenous diet.	Improved.
5	Mr. K——, aged twenty-eight; single; accountant.	Spinal pains and weakness; easily fatigued; can't concentrate thoughts; has had to give up business; cold hands; anæmia; some dyspepsia; occasional emissions.	Urine clear, acid, 1.030; no sugar or albumin; urates in excess, phosphates normal (eight trials).	Nitrogenous diet; Blaud's pills; mercurial laxatives.	No improvement; urates disappeared.
6	Mr. S——, aged thirty-five; married.	Has had several attacks of acute rheumatism; has a mitral lesion; of late has periodical headaches (vertical); insomnia or bad sleep; great mental irritability and depression; nervousness; slight dyspepsia; sometimes has muscular rheumatic pains.	Urine clear, acid, 1.024; urates in slight excess, phosphates average.	Potas. bicarbonate.	Very great improvement.
7	Mr. C——, aged forty-five; married.	Father neuralgic; has had severe malarial poisoning and ague-cake; in late years has had three severe falls (from a wagon); has had no rheumatism or gout; now has tender and painful spine; muscular pains and soreness; tinnitus; bad sleep; very nervous, excitable; worried at times; easily tired; can't exert mental faculties.	Urine clear, acid, 1.024; urates in excess, phosphates average; no sugar or albumin.	Bicarbonate of lithia and potas.; blister to spine; rest.	Great improvement.
8	Mrs. D——, aged forty-five	Mother rheumatic, and all the eight brothers and sisters rheumatic; father died insane; patient never had rheumatism; of late very nervous, excitable, hysterical; confusion of mind; loss of memory; some rheumatic pains in shoulders and legs; anæmia; dyspepsia; has been treated for prolapse and anteversion of uterus.	Urine very cloudy; excess of urates was very marked (two tests), phosphates below average.	Nitrogenous diet; laxatives, Blaud's pills or tartrate of iron and potas.	No improvement at all.

slightly in excess; another test showed a greater excess of urates. She did not improve much on acid tonics and bromides, but improved, though temporarily, on Blaud's pills and on alkaline salts.

A professional gentleman, aged about thirty-three, who had had several attacks of acute rheumatism, came to me complaining of what he called cerebral neurasthenia. He was a man of strong physique, ruddy complexion, and full habit. He had a mitral lesion as the result of his rheumatism. He complained of periodical headaches, parasthesia, vertigo, lassitude, great mental irritability. He had at times passed urates in excess. His urine was

cases. It is well known that many persons live on the verge of a gouty paroxysm for years, and yet have no marked nervous symptoms. Dr. Murchison, in his description of lithiasis, does not describe the nervous symptoms of latent gout, although England is full of it. Both Anstie and Eulenberg speak in most positive terms against there being any causal relation between gout and neuralgia.

It is probable that we see here again the running together of the nervous and rheumatic diatheses, or at least that we have a dyscrasia which is not identical with that of gout, though allied to it.

All the same the view of a humoral origin of certain chronic nervous disorders is a fruitful one, from a therapeutic stand-point, and Dr. Da Costa has done great service in recalling attention to it. My experience so far teaches that in a good many cases of neurasthenia, especially of the gastric type, of hysteria, of spinal irritation in its lighter forms, and, in general, of great nervous irritability, there is an unsuspected excess of uric acid in the urine and blood, or, perhaps, some latent rheumatic taint. Treatment addressed to this will often succeed in giving prompt relief.

The subject of phosphaturia, so-called, is in a state of some confusion. Here again it was Dr. Prout who first associated a tendency to the deposition of earthy phosphates in the urine with conditions of depression and nervous irritability. Dr. Hassell also attributed grave constitutional symptoms to the precipitation in the urine of the crystalline phosphate of lime. Subsequent observers, however, and especially Bence Jones, have shown that in these cases of cloudy urine with deposition of phosphates the trouble is generally due to a diminished acidity of the urine, and not necessarily to excess of the salts. Any urine that for some cause becomes alkaline becomes cloudy and deposits its phosphates. It has been further shown that both an increase in the earthy phosphates and a diminution in the acidity of the urine can be caused merely by changes in diet, by acute, exhausting diarrhœas, or even by temporary attacks of indigestion.

So that of late it has been generally taught that there is no such thing as phosphaturia, or the phosphatic diathesis, but that this was all simply a question of diet and digestion. Dr. Dickenson, while admitting this view, still thinks that there is a condition of exaggerated nervous mobility, irritability, and exhaustion associated with the discharge of an excess of earthy salts. The urine here, he says, is not generally turbid, however, but is clear and yellow. It may even be extremely acid and scalding. There are rarely any deposits except occasional lithates or oxalates. The patients suffer from obscure arthritic pains, vertigo, parasthesia, tinnitus, melancholia, and their condition is often suspected to be one of latent gout. Yet they are made worse by salines, and generally improve under strychnia and mineral acids. Dr. Dickenson appears to be describing, under the head of phosphaturia, a clinical condition surprisingly like that described by Dr. Da Costa under the head of lithæmia or American gout. It is to be greatly regretted that neither of these observers gave comparative estimates of the amount of the earthy salts and of the urates.

In my own experience I do not find that in a majority of cases of nerve-irritation and depression there is any great and persistent excess of the total phosphates excreted, though there is often a diminished alkalinity and cloudy urine. It is a common observation that persons who suffer from dyspepsia and nervous asthenia, will pass cloudy urine after some unusual amount of mental work and worry, or after some dyspeptic attack.

Sometimes these cloudy urines really contain an excess of phosphates, but I have not yet found that it is the rule. My observations on this point are not finished.

As to the significance of those disturbances of the urine, my own opinion is that this so-called phosphaturia, when it occurs, is the result either of a peculiar diet, or of an indigestion due, perhaps, to insufficient innervation of the digestive organs, just as glycosuria and lithæmia may be due to insufficient innervation of the liver.[1] The careful experiments of Mairet (*Archives de Neurolog.*, January, March, and June, 1885) have shown that intellectual work and pathological irritations of the central nervous system slightly increase the excretion of the earthy phosphates, but do not especially change the excretion of the alkaline phosphates.

Treatment, directed to the nerves and stomach (strychnia, mineral acids), will usually very quickly relieve phosphatic urine.

From what has been said it is apparent that it is of the highest importance that the practising physician make himself acquainted with the condition of the urine as regards its phosphatic salts and its uric acid.

Certainly no case of chronic functional nervous disorder can be intelligently treated without such examination.

Here is a case in point: M. H——, aged thirty-two, married, suffers from frequent vertiginous attacks, periodical headaches, great nervous irritability, hysterical crises. Has a badly lacerated cervix. Had been long treated by various measures in vain. A gynecologist at last said she must be operated upon for the laceration.

I found the urine very acid, cloudy with urates (in four specimens). Treatment addressed to this (alkalines and stomachic tonics) gave her not perfect, but very great relief.

In order to facilitate the making of the proper urinary examinations, I have devised an apparatus which enables one with very little trouble to get an approximate idea of the relative amounts of phosphates or of uric acid.

I have several small glass tubes, thirty inches long, one and an eighth inch in external circumference, enlarged at the ends in a funnel shape, and stopped at one end by a rubber cork. These are graduated to fifteen and twenty-five cubic centimetres.

I have taken an artificial solution of triple phosphates of the strength of the average urine (0.5 per cent.), and precipitating the salts have marked the upper line on the tube. I have also, in a large number of cases of normal urine, obtained about the line of an average precipitate of phosphates.

In order to precipitate all the phosphates, both earthy and alkaline, I fill the tube with a definite quantity of urine, and then add Teissier's solution to saturation.

℞.	Aquæ destillat.	80.0
	Ammon. chlorid.	20.0
	Aq. Ammon. fort.	20.0
	Magnes. sulph.	20.0
M.		

One cubic centimetre of precipitate equals about 0.63 of phosphates per litre.

The solution should be renewed occasionally, as it loses some of its strength in standing.

If one wishes to precipitate only the earthy phosphates, he adds simply ammonia. Afterward he can add Teissier's solution, and observe the amount of alkaline phosphates. By this method one can very readily and quickly recognize approximately an excess in phosphate deposit as a whole, or in earthy deposit.

Despite a great deal of experimentation I have not been able to find any better ready test for the uric acid than that by hydrochloric acid.

To determine the amount of the uric acid, therefore, I

---

1 Nutrition [illegible] NEW CLASS [illegible] Nerves.—It is [illegible] established [illegible] the nerves [illegible] tissues [illegible] in a state [illegible] healthy [illegible] finally, that upon its integrity depends the function of sensation and reflex action.

Hence pathologists classify symptoms of functional disorders into:

1. The motor and vaso motor neuroses, *e.g.*, paralyses, spasms, etc.
2. The trophic and secretory neuroses, *e.g.*, progressive muscular atrophy, certain skin eruptions, hyperidrosis, etc.
3. The sensory neuroses: neuralgia, hyperæsthesia.

There are certain disorders of assimilation in which metabolism does not go on properly. They are conditions which sometimes come on when the nervous system is poisoned, exhausted, or asthenic. They are caused most likely by the nervous centres not giving to the special metabolic tissues the normal tonic and regulatory impulses. There is in consequence a "metabolic" disorder; just as from deficient innervation there is motor weakness or some secretory disorder. In fine, we have a fourth class of the neuroses, the *metabolic neurosis*. Glycosuria, lithæmia, azoturia, and perhaps "phosphaturia," are included in this head.

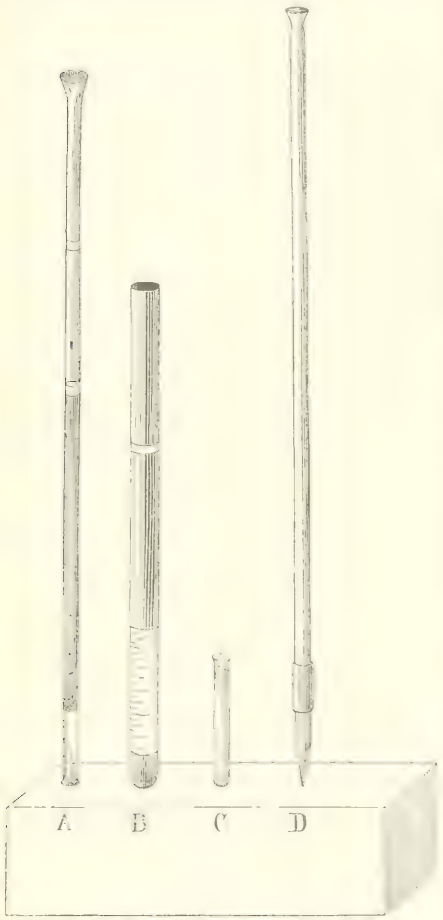
I believe there can be no valid objection to the view thus presented. It is a fundamental law of biology that the nervous system in the higher animals controls and regulates all the different bodily functions. The function of metabolism is the oldest in the history of animal life, and though not sharply specialized and relegated to a [illegible]

Metabolism and tissue-nutrition are not identical, although in its broadest sense metabolism includes nutrition. But in the more special sense, in which I use it, it refers to the livens-consumption of material that circulates in the system, never going to form tissue; the process that is most active in the liver, spleen, and in adenoid and adipose tissue, to all which Foster gives the name metabolic.

A [illegible] a very different thing from a trophoneur[illegible] like a spinal affection of a motor filament.

fill the tube with 15 c.c. of urine, and add 10 c.c. pure muriatic acid, then let it stand for twenty-four to forty-eight hours in a cool, dark place. Normally the amount of uric acid in 15 c.c. of urine is between gr. $\frac{1}{12}$ and gr. $\frac{1}{10}$. This, when precipitated, makes only a few dark specks at the bottom of the tube.

By making a solution of uric acid of the same strength as that of the urine, and then precipitating it, and by numerous tests with healthy urine, I get a very fair idea of the appearance of a normal precipitate. It is an excess when the whole bottom of the tube is covered, and even in clear urine I have seen the precipitate reach $\frac{1}{16}$ of an inch in depth, measured along the tube.



A is the tube ordinarily used. B, one with a funnel-shaped point. C, one in which the upper end is closed with a cork. D, a large tube for the quantitative estimation of uric acid, and for the urinary deposit.

In order to get, if possible, a more accurate measure, I had a funnel-shaped point jointed on the tube instead of a simple cork. This did not seem to work so well.

I am quite aware that the muriatic-acid test is said not to be very accurate, but it seems to me to answer all the purposes, and I find that, used in the long tubes, kept standing erect in the dark and in a cool place, I have no difficulty in getting a precipitate. In test solutions of uric acid I get nearly or quite all of the acid precipitate.[1]

[1] These tubes can be obtained of Mr T. H. Smith, corner Forty-Sixth Street and Sixth Avenue, Sayre's Pharmacy.

By the systematic use of these two tests, which should always be applied several times in each case, using both morning and evening urine, I believe that much help can be obtained in diagnosis and in the treatment and general guidance of the patient. If a persistent excess of phosphates is found without any excess of urates, the use of mineral acids and strychnia will be very surely beneficial. On the other hand, it is very likely that one reason why acids sometimes fail to relieve cases of apparent phosphaturia is that this condition does not really exist.

If acid urine, with high specific gravity, and excess of uric acid are found, a nitrogenous diet, alkalies, cholagogues, stomachic tonics, and stimulants are indicated. Sometimes diet alone is sufficient, and drugs are not tolerated.

It is to be borne in mind all the time that occasional deposits of urates may be due simply to cold weather and digestive disturbances, and may mean nothing.

In conclusion, I would sum up my remarks as follows:

1. There is no such thing as a lithæmic or uric acid diathesis, or as an oxalic acid or phosphatic diathesis.

2. There are, however, morbid conditions of the nervous system which are associated with excessive acidity of the urine and excess of uric acid in the urine. The morbid nervous symptoms in these cases are those of gastric neurasthenia, lighter forms of spinal irritation, great nervous irritability, vertigo, headaches, bad sleep, hypochondriasis, etc.

3. The "lithæmic state" is one that is allied to gout and rheumatism, rather than identical with either.

4. The lithæmic state in question, associated with nervous symptoms, is generally brought on by some overstrain or draining of the nervous system, or by some chronic poisoning of it, as by malaria or lead. It is probably a trophic or metabolic neurosis comparable to diabetes.

5. Oxaluria is generally only a form or indication of lithæmia. When oxalate of lime occurs in abundance with deposits of earthy salts, it has no clinical significance.

6. Phosphaturia, or an excessive deposit of earthy and alkaline phosphates in the urine may be only apparent, and due to deficient acidity of the urine from excess of vegetables or fruits in the diet. But an excessive discharge of phosphates may accompany conditions of functional nervous depression and irritation. It indicates in these cases a disturbance of digestion, due perhaps to some perversion of the innervation of the digestive organs. If kept up, the loss of phosphates and undue alkalinity of the blood may react upon the nervous system, but in the vast majority of cases phosphaturia is only an evidence of indigestion.

7. It is of great importance for purposes of diagnosis and treatment of chronic functional nervous disorders that a careful study of the acidity and alkalinity of the urine be made, and that the proportions of urates and phosphates discharged be estimated.

52 West Forty-Sixth Street.

Illegitimacy in Lima.—The Peruvians seem to have a positive aversion to matrimony, if statistics prove anything. In the register of births for the month of August last, published in *El Monitor Médico*, of 392 children, 208 were illegitimate, 177 legitimate, and 7 doubtful. Of the negroes, 90 per cent. were illegitimate; of the pure-blooded Indians, 68 per cent.; of the mixed race, 60 per cent., and of the whites, less than 29 per cent. It is to be noted, however, that many couples live together as man and wife, and are faithful to each other, although they have not gone through the ceremony of a formal marriage, and their children are consequently recorded as illegitimate.

Miss Alcott remarked during a trip on an ocean steamer: "They name ships Asia, Persia, and Scotia. I wonder it doesn't occur to somebody to name one Nausea."

ANNUAL REPORT OF THE THROAT DEPARTMENT OF THE GERMAN DISPENSARY,

With Remarks on the Treatment of Laryngeal Phthisis, and on Reflex Neuroses due to Nasal Disease.[1]

By J. W. GLEITSMANN, M.D.,

[illegible]

Before entering into the subject proper of my paper, allow me to say a few words about the work done in the Throat and Ear Department, which, as you all know, was the last one to be created as an independent class. When I was assigned to duty in the fall of 1882, the department was still combined with the eye class. A record from the books shows the total number of patients during 1883 to be 3,274, of whom there were 1,407 throat and ear patients. The formal separation from the eye class took place on May 23, 1884, when we moved into our comfortable new building. The number of throat and ear patients during 1884 was 2,219, an increase of fifty-seven per cent. compared with the year previous; during 1885, 3,156, showing an increase of forty-two per cent. over 1884. When you compare the increase of patients in our department with that of the other classes during the last three years, the rapid growth of the former will be still more apparent. Although I may be permitted to say that all the surgeons worked with equal zeal and devotion, the great influx of patients is certainly in a large measure also due to the fact that a separate and distinct department had been created for this class of diseases. The attention of the public once being attracted, a greater number sought help for their ailments.

The report which I now lay before you does not contain the total number of patients, the ear cases being excluded. My intention to treat of the latter at another time, and the fact that the laryngological and rhinological material will more than suffice to occupy our evening, may serve as my excuse.

I am well aware of the shortcomings of statistics like the present; they necessarily suffer from imperfections time only can eliminate. The figures are too small, the time of observation is too short, to allow conclusive deductions in regard to the frequency of a disease, the etiological factors, the influence of sex, seasons, etc. Nevertheless, aside from a review of the work done in the department, the reader will find many interesting data, and if others will publish similar reports in the future, their value will naturally be enhanced. Up to the present time only few statistics of this kind have appeared. Among them I may mention the reports of the Throat Department of the St. Thomas' Hospital, in London, for 1882 and 1883, by Dr. F. Semon, and Dr. Schmiegelow's first report of the Commune Hospital in Copenhagen, published March, 1884. No such compilation, as far as I know, has been made in this country.

The classification of patients under the different headings was rendered the more difficult, as three surgeons succeeded each other during the course of the year on the three alternate working days. A perfect uniformity in the nomenclature could not, therefore, be expected. Further, in many instances a patient suffered from more than one affection at the same time. In order not to complicate the report too much, each patient is enumerated but once and classified according to his most prominent ailment.

Of the total number of patients 2,042 are contained in the different tables; the majority of the other 1,114 were suffering from ear complaints. To many treatment was refused on account of their being found able to pay, and several were assigned to other departments, to which they properly belonged. The 2,042 patients were divided into four groups, and we count, under diseases of the pharynx, 1,100; of the larynx and trachea, 392; of the nose and rhino-pharynx, 493 patients. The fourth group, which strictly does not belong to our specialty, comprises 57 patients, suffering from diseases it was considered opportune to treat in the department.

From the sixty-nine different diseases in the tables before you I have selected two topics which I thought of sufficient interest to engage your attention this evening, viz., the treatment of laryngeal phthisis and the reflex neuroses due to nasal disease. In order not to transgress the allotted time, I shall be brief and only mention the salient points.

It always has been the endeavor of physicians to treat laryngeal phthisis successfully. While some writers, as, for instance, Tevishaber,[1] Heinze,[2] believe in temporary relief only, the majority of observers consider a permanent cure possible. Some of the latter, for instance, Mackenzie,[3] Cohen,[4] regard cure as an exception; others, as Bosworth,[5] Schmidt,[6] report very favorable results. The former has cured sixty cases, the latter nineteen of three hundred and fifteen patients seen within three years, and nine of eighty-seven seen later. But while Bosworth holds the opinion that laryngeal phthisis is not necessarily of tubercular origin primarily, and that tubercle as a rule plays no part in its primary causation or development,[7] Schmidt agrees with Heinze as to its tubercular nature from the beginning, and calls only such patients cured who remained free from laryngeal and pulmonary symptoms for a long period.

In order to combat the local complication successfully, treatment of the pulmonary affection is absolutely necessary. It will here suffice to merely mention the measures to be adopted: as climatic treatment, due attention to the skin, suitable nourishment, avoidance of dust, and rest of the vocal organs.

It was thought that with the invention of the laryngoscope a more successful treatment could be inaugurated, but the expectations were not realized. Astringents and caustics were first employed, but were soon abandoned as too irritating, and as failing to change the malignant nature of the ulcerations. When, in 1860, atomization was introduced, the remedies were applied in spray form. Resolvents, astringents, and recently antiseptics have been recommended, as boracic acid, carbolic acid, also creasote, thymol, oil of turpentine, with or without addition of narcotics.

Schmidt ascribes his good results, mentioned above, to the inhaling of disinfectant and antiseptic vapors. Eight to fifteen drops of a mixture of ten parts of balsam of Peru and five parts of rectified alcohol are put into half a litre of boiling water, and the patient is directed to inhale the vapor for five minutes three to four times daily. Antiseptics can also be inhaled for a longer time through respirators, Herschmann's mask. In order to avoid the irritation of mouth-breathing, Whistler devised a pattern which allows inhalation through the nose only, and later added an instrument for the same purpose for patients on whom tracheotomy had been performed.[1] He chiefly uses conium, turpentine, camphor, eucalyptus oil.

The same class of remedies is also applied locally with the cotton-carrier or powder-blower. The best results have been obtained with boracic acid and iodoform. As boracic acid has been superseded by the iodoform, I shall confine my remarks to the latter. Lincoln employed iodoform as early as 1873,[2] and in 1878 it was in use in the London Throat Hospital. In Germany Schmidt induced Beetz[3] to make the first insufflations in laryngeal phthisis with good results. Iodoform is at present the most favorite remedy with the majority of laryngologists, although it has some drawbacks. Some patients lose their appetite, and Fraenkel[4] not long ago stated, in a meeting of the Berliner Medical Society, that iodoform does not kill the bacilli.

Quite recently Krause recommended lactic acid[6] and praised very highly its beneficial effect. His attention was drawn to this remedy by Mosetig-Moorhof,[6] who destroyed superficial epitheliomata, and papillomatous and fungous growths by the concentrated acid. The advantage lactic acid possesses over other caustic remedies rests in its property of destroying diseased tissue, leaving the healthy parts intact. In order to obtain the full effect of the acid, it is necessary to employ it in concentrated state, and to leave it in contact with the tissue for some time. Krause adopted this procedure as far as possible to the laryngeal application by rubbing the solution into the affected parts, and by rapidly increasing the strength from ten to fifty, even eighty per cent. He reports fourteen cases, some very severe, with extensive ulcerations over the greater part of the larynx, and then summarizes as follows: After the application of strong solutions a tough scab is seen adhering firmly to the ulcers. The swelling and infiltration decreases, and after the sore clears up, healthy granulations appear. The ulcers become smaller, cicatrization commences, dysphagia disappears, and the voice and general condition improves. In a later communication[7] Krause relates favorable reports received by Gottstein and Hering, and quite recently Jelinek[8] corroborated these statements. The discussions following these last two papers developed considerable opposition, and opinions are widely divided at the present time.

The desire to judge for myself as to the utility of this treatment, induced me last fall to adopt it in my department.

Only such patients were selected as had positive signs of pulmonary complications and well developed laryngeal symptoms, such as tubercular infiltration or ulceration. The histories are, in brief, as follows:

CASE I.—Female, aged thirty-eight. Cavity in right apex; slight hoarseness and small infiltration on posterior wall of larynx. Treatment began October 28th. December 29th the laryngeal swelling had grown smaller, but had not disappeared entirely, voice better.

CASE II.—Male, aged thirty-one, upholsterer. Dulness and moist râles at left apex anteriorly; considerable tumefaction of the arytenoid cartilages; conical excrescence on posterior wall of larynx; hoarseness, no dysphagia. Persistent treatment for two months with strong solutions resulted in but slight decrease of the posterior infiltration.

Case III.—Male, cabinetmaker, aged thirty-eight. Cavity in right apex; hectic symptoms; large œdematous swelling of left ventricular band, its posterior third destroyed by deep, angry ulceration; dysphagia. Patient had been treated with iodoform and cocaine without visible effect. Lactic-acid treatment begun October 28th. After two weeks the ulcer was perfectly clean and cicatrization had commenced; marked improvement. End of November, slight infiltration of left aryteno-epiglottic fold and left vocal cord, which were in statu quo December 29th, the patient being irregular in his calls. The first ulcer remained healed.

Case IV.—Male, aged forty-six, works in a brewery. Right lung diseased; infiltration of intra arytenoid region. Ulceration began while under iodoform treatment; odynphagia. Lactic acid lessens the pain and cleans the ulcer, but during its use the process extends to the epiglottis, and patient goes to a hospital, where he dies.

Case V.—Male, machinist, aged forty-nine. Right lung affected; superficial erosions of the free border of both vocal cords; slight infiltration of ventricular bands anteriorly; hoarseness. No visible effect of treatment.

Case VI.—Male, cigarmaker, aged forty-one. Right lung diseased; larynx shows swelling of the left arytenoid cartilage and slightly ulcerated cords. Patient at first bears only weak solutions, but in spite of strong applications during one month the right arytenoid and both ventricular bands had become infiltrated. Dysphagia had decreased.

Case VII.—Male, aged thirty-two, clerk. Dulness, moist râles at right apex; left edge of the epiglottis slightly tumefied, ulceration extending through the mucous membrane to the cartilage; severe odynphagia. Treatment begun November 14th, with solutions of ten per cent., rapidly increased to twenty-five and fifty per cent. Two weeks later the ulcer had cleared and pain in swallowing disappeared. Middle of December ulceration began on the right side of the epiglottis, and one application of seventy-five per cent. was made. Patient complained of great pain during the week following, but felt relief after three subsequent insufflations of iodoform.

Case VIII.—Male, aged thirty-two, porter. Affection of both lungs. The whole larynx one large ulcerated surface; extreme odynphagia. Patient was irregular in his calls, and no perceptible effect of the treatment could be observed.

A ninth case, although not properly belonging here, deserves mention. The patient, male, aged forty-six, had no physical signs of lung disease, and careful microscopic examination of his sputa as well as laryngeal secretion showed no bacilli. But the ulceration of the epiglottis and a deep ulcer on the posterior part of the left ventricular band, extending to the cord, made the diagnosis of phthisical laryngitis most probable. After one month's treatment the ulcer was clean, and dysphagia relieved. Patient died soon afterward from intercurrent pneumonia; no post-mortem allowed.

These observations will justify the following conclusions:

1. Lactic acid is a valuable remedy in most cases of phthisical ulceration of the larynx. The ulcers heal rapidly and the distressing pain in swallowing is thereby relieved.

2. Its use does not prevent the formation of new infiltrations, or ulcerations.

3. When not combined with other proceedings, it has little or no effect on infiltrations, which are covered by intact mucous membrane and epithelium.

The last subject of my paper, the reflex neuroses due to nasal disease, has of late engaged the attention of medical writers to such a degree that I have thought it of sufficient interest to give you a short review.

Distinction has first to be made between normal and pathological reflex phenomena. To the former belong sneezing, caused by inhalation of dust, introduction of irritating powders into the nose; epiphora, produced by similar causes; further, the reflex relation between mucous membrane and respiration and circulation, described by Kratschmer.[1] When a quietly breathing rabbit is made to inhale the vapor of a volatile liquid, *i.e.*, ether, ammonia, etc., the thorax assumes the expiratory position and the heart ceases to beat. Finally, cough can be elicited by irritation of a normal nose, for instance, contact with a probe—a question recently exhaustively studied by Mackenzie.[2]

The first observation of pathological reflexes was made by Voltolini,[3] who cured a patient of asthma by extirpation of nasal polypi. He soon was followed by others, for instance, Haenisch,[4] Porter,[5] who effected a cure of asthma by removal of a pharyngeal polypus; but it was left to Hack to draw general attention to the subject.[6] Although he seemed at first too enthusiastic, and was obliged to modify his views later on, he certainly deserves the credit of having pointed out a group of diseases due to nasal affections, and of having thereby made them amenable to treatment. The present state of the question is, in a few words, as follows:

It has been well known for some time that there exists a cavernous erectile tissue on the lower and middle turbinated bones of the nose, an excellent description of which has recently been given by Zuckerkandl.[7] This tissue can be irritated and made turgescent by reflexes arising from other parts of the body, and by morbid local changes, and then produce neurotic symptoms. The neuroses are generally transmitted by the first and second branch of the trigeminus, but the olfactory also plays its part; it is, for instance, known that an asthmatic attack has supervened on entering a room containing violets.

Of the reflexes which are produced by transmission from outside sources, I may mention sneezing after looking into a glaring light, for instance, sunlight, and filling of the nasal vessels with the sensation of stuffiness after exposure of the skin to cold. The psychical sphere and genital tract also sometimes exert their influence on the erectile tissue, which fills with some women during menstruation.[8]

The observation that many patients with nasal hypertrophies have no reflex symptoms, is explained by Rossbach on the assumption that the nervous system of such sufferers is similar to that of neurasthenic and hysterical people. The lower turbinated are most frequently diseased; next, the lower and middle combined; last, the middle ones alone. The disease is more frequent in the better situated than poorer class, and, contrary to adenoid vegetations, more in adults than children.

We can distinguish several forms of reflex neuroses, the most frequent of which are: (1) spastic neuroses, as bronchial asthma, spasmodic sneezing and coughing, also glottic spasm; (2) neuroses of the sensory sphere, as abnormal and painful sensations in the pharynx and larynx, hemicrania, supra-orbital neuralgia, alopecias in remote parts of the body; (3) of vaso-motor reflexes we have erythema of the nose, œdema of the face, erysipelatous swelling of the eyelids and cheeks. To this group can also be referred attacks of vertigo, and, according to the opinion of most American writers, the hay fever; (4) serous neuroses manifest themselves in profuse, sudden, serous secretion from the nose, in epiphora, which in this case is not brought on by mechanical obstruction of the lachrymal duct; finally, salivation. Further, there have been observed scotomata, palpitation of the heart, epileptoid attacks, etc. Sommerbrodt[9] published the case of a boy who had œdema of the face, spasmodic sneezing, profuse nasal secretion—all men-

tioned above. Further, he suffered from reflexes to the bronchial vessels with all the physical signs of chronic bronchitis; from reflex vomiting and reflex involvement of the nerve-fibres of the skin, causing chilliness, rigor, paleness. After a few days of treatment of both lower turbinated bodies with the galvano-cautery he showed improvement, and was entirely cured within one month.

The prognosis is better for the local symptoms arising from the nasal affection, as coryza, epistaxis, inflammatory conjunctivitis, than for the reflex phenomena. Therefore it is best to be reserved in the opinion expressed to the patient.

When there is doubt if the neurotic symptoms are due to nasal disease, the use of cocaine can help the diagnosis, as cases are described in which the reflex neuroses were temporarily suspended after application of cocaine to the nasal hypertrophies. Cocaine, besides its analgesic and anæsthetic properties, also has the effect of depleting the cavernous erectile bodies. Even weak solutions cause collapse of the turgescent tissue, and the mucous membrane can be seen to adhere close to the bone. Bosworth was the first to draw attention to this fact, which already has been found useful in the treatment of various nasal affections.

Before resorting to the actual cautery, milder means can be employed to remove the hypertrophies, as, for instance, glycerole of iodine, iodide of zinc, of caustics, nitric acid, chromic acid, glacial acetic acid, etc.; but our chief dependence will always remain the galvano-cautery, on account of its quick and positive action. By applying cocaine before and after the operation, not only will pain be avoided, but the patient will also escape the distress caused by the swelling and stuffiness following the application of the cautery without this precaution.

KERATOSIS SEBACEA—A CASE ASSOCIATED WITH HYPERTRICHOSIS.

By GEORGE T. ELLIOT, M.D.,

[illegible]

THE literature of this dermatosis is very misleading and confusing, owing partly to the variety of names under which it has been described, and partly to the very different diseases which have been confounded with it. The term Ichthyosis sebacea seems, however, to be the one in most general use, notwithstanding that it is also given to processes which have no connection with the sebaceous glands, as, for instance, keratosis diffusa intra-uterina.

Seborrhœa squamosum neonatorum, Xeroderma saurioides, Cutis testacea, Ichthyosis congenita, Seborrhœa universalis, Acné sebacée, etc., are still further designations which are made synonymous with each other and with ichthyosis sebacea. Yet the processes which are included under these are in many cases very different, not only from each other, but also from keratosis sebacea, and one is at an utter loss either to reconcile them together, or to regard them as dependent even in a remote degree upon the same cause. Affections due to an anomalous development of the epidermis, dating from early intra-uterine life, as in ichthyosis congenita, those having their origin in an excessive and abnormal secretion of vernix caseosa, as in seborrhœa squamosum neonatorum, and those arising from an inordinate action of the fully developed sebaceous glands, accompanied by an exfoliation of their epithelium, as in keratosis sebacea, are thus found jumbled together, regarded as being more or less the same, and dubbed with a name, ichthyosis sebacea, common to and interchangeable between them all. The confusion which results from this is necessarily antagonistic to any clear comprehension of the subject, and brings the reader into a condition of utter perplexity.

I shall scarcely, however, in this article, attempt to elucidate the differences existing between the various affections bearing the name ichthyosis sebacea, my intention being only to describe a case which is interesting from its rarity, and from an unusual feature accompanying it. That I use the term keratosis sebacea, instead of ichthyosis sebacea, is owing to the confusion surrounding this latter, and because it expresses most clearly the nature of the changes which occur in the course of the affection.

Lebert ("Ueber Keratose," Breslau, 1864) defines keratosis sebacea as a species of seborrhœa which differs from ordinary seborrhœa in that it is accompanied by more extensive exfoliation of the epithelium of the sebaceous glands, the affection being primarily dependent upon an enormously increased secretion of sebum, and upon epithelial hyperplasia. Keratofication is secondary, and results from inspissation and desiccation of the secreted mass.

There are rather few descriptions of keratosis sebacea given either in text-books or in journals. Of these the most accurate is that of Erasmus Wilson, which is quoted in extenso by Lebert. Biefel, likewise, under the name of ichthyosis spuria, and Schwimmer, under that of seborrhœa universalis, each describe a case agreeing perfectly with Wilson's, and distinguishable for accuracy and clearness. Reference to the affection, and mention of the process is also given by many others, but these observers are the only ones whom I have found treating it with definiteness and thoroughness.

The cases described by them leave no question in regard to the sebaceous origin and nature of the affection. Biefel and Schwimmer held that it was situated entirely in the glands which secrete sebum, and Wilson, though considering it a form of ichthyosis, yet believed it to be one in which the sebaceous glands played a principal part. As Lebert says, there is an exfoliation of the epithelium of the glands which occurs before the cells have undergone complete fatty degeneration, and these, arriving upon the surface mixed up with the sebum, undoubtedly aid in producing the incrustation. But yet there is no connection between this exfoliation and the epidermic changes seen in ichthyosis, which depend upon an anomalous development of the epidermis. In the one, the horny appearance acquired by these exfoliated cells is entirely secondary, and due to a process of desiccation, but in the other the cells are true epidermis cells, which have been produced in the natural manner, only deviating in their arrangement from the norm. In addition, in keratosis sebacea there is no hereditary tendency, while in ichthyosis it is absolutely established. Besides, as will be seen presently, the objective symptoms presented by this affection separate it very distinctly from those which belong properly to the ichthyoses. In its development, keratosis sebacea seems to follow no definite rule. At times appearing shortly after birth, at others not until adult life has been reached, it seems to be limited to no particular age, but to occur at any time in post-uterine life. Biefel's patient was twenty-two years of age when first seen by him. The affection had been more or less present since childhood, but rapid and extensive increase had commenced only at the age of nineteen. Wilson mentions two sisters, seen by Dr. Ogle, in whom the process developed at the age of fourteen, following vaccination. It may be universal, or limited to only small areas, or again consist of only a few patches.

The first changes observed in the development of keratosis sebacea consist in a largely increased secretion of sebaceous matter. It is, as it were, poured out upon the skin, accumulating rapidly and becoming gradually inspissated, until it forms a hard and dry incrustation. The color, at first only grayish, becomes gradually brown, and then darker and darker, until it varies from a deep brown to even a black or greenish black. This change in color is due both to deposition of dust upon the surface, and also to pigment mixed with the secreted sebum. The incrustation is not uniform, but is cracked

and broken into pieces of variable shape and size, which, though externally hard, horny, and of dark color, yet are softer as the surface of the skin is approached, and contiguous to it are quite soft and fatty, and light gray. On removing some of the mass, the skin is found normal in appearance, or perhaps slightly reddened, but the ducts of the sebaceous glands are dilated and patent. The general health of the patient is usually unaffected, and only the objectionable appearance of the evil is complained of.

This brief *résumé* of the principal features of keratosis sebacea is, I think, sufficient to identify it with the following case. This latter presented, in addition to these symptoms, however, one, as already mentioned, which materially increased the interest excited by the unusual affection.

W——, a boy, aged seven months, born in New York, of German parentage, was brought last June to Dr. Bulkley's clinic at the New York Skin and Cancer Hospital. The baby was well nourished, fat, and playful. He nursed well, his bowels were in normal condition, and he was evidently in perfect health. His parents, also, were strong and healthy, and their other children were entirely free from any affection of the skin. Besides, they knew of no one connected with their family who had suffered or were suffering from any similar or correlative process. The baby's skin had been, at birth, perfectly normal, and had remained so up to the age of six weeks. At that time diffuse, irregular, but distinctly limited erythematous patches began to appear upon both ankles and the dorsal surfaces of both feet. They were not elevated, and were entirely free of squamæ. In a few days, however, these patches were found covered with thin, whitish, easily detachable and soft scales, which, notwithstanding repeated washing, accumulated rapidly, became thicker and harder, and underwent changes in color until they were of a dark brown or black. Almost immediately after the appearance of the patches on the feet and ankles, the erythematous condition began to extend upward upon the legs, until it occupied the entire lower extremities. The formation of scales upon them ensued in the same way as upon the first patches. The process likewise developed itself in a few places upon the body. The child's health remained perfect all this time.

Status præsens.—On removing his clothes, the little patient presented the following condition: The dorsal surfaces of the feet, and the entire lower extremities as far upward as Poupart's ligament anteriorly, and the gluteal fold posteriorly, with the exception of an irregular, diamond-shaped space occupying the popliteal region, were entirely covered by an incrustation of a dark-brown and greenish-black color. This shaded off toward the plantar surfaces of the feet, which were entirely free, in thin, light-brown scales. The upper surfaces of the first and second phalanges of the toes were also more or less covered by thick, dark, hard squamæ. The incrustation was not uniform, but divided up into small pieces of various shapes and sizes, none being larger than a small grain of corn. They were elevated above the skin from one-sixteenth to one-tenth of an inch, and their external surfaces were slightly convex, and polished from friction. Each small piece seemed to fit into the other, and offered no hinderance to the natural movements of the child. The encasing sheath on the extremities resembled very much a mosaic in dark brown. The scales were rather adherent, but on removing some of them, nothing but a slightly reddened appearance of the skin was observed.

The penis, scrotum, and perineum were entirely free, as also a narrow line along the inner margin of the inguino-scrotal space. The buttocks were the seat of only a diffuse redness, which extended upward as far as the second lumbar vertebra. The irregular border which bounded this diffuse patch was, however, covered with brown scales, and their absence from the buttocks was probably due to the manner in which the child was carried. Irregularly shaped spots, varying in size from a twenty-five-cent piece to the palm of the hand, were also seen here and there on the abdomen and back, some only erythematous, others covered with light-brown squamæ. The backs of the hands, the wrists, and the arms, as far up as the elbows, showed diffuse redness, with here and there accumulation of brownish and black scales. The incrustation is not so uniform upon the upper extremities as it is upon the lower; the scales are not so thick, nor are they so closely aggregated together, and they are found more upon the extensor surfaces than upon the flexors. The palms of the hands are entirely free. On the neck, again, we find three or four distinctly limited oval spots, varying in size from a twenty-five-cent piece to a silver dollar, and upon the cheek one measuring two inches by one and a half inch. These last show only a condition of erythema, are devoid of squamæ, and are soft, velvety, and slightly oily to the touch. Over the anterior portion of the right parietal bone a patch is situated, which presents the same appearance as seen on the legs. The skin between all of these discrete patches is white and soft, and seems to be in every way perfectly normal.

On removing some of the incrustation, which, externally, was hard and dense, it was seen that it became gradually softer as the skin was neared, the color at the same time becoming grayish. They crumbled rather easily under pressure, with the exception of the outermost layer, which resisted even considerable force. Examined under the microscope, they proved to be composed of: Sebaceous matter in great quantity; oil-globules; horny cells (some diffusely pigmented, others containing only pigment granules); free pigment; cholesterin crystals in large numbers; foreign matter.

Diachylon ointment was prescribed for the little patient, and the mother was instructed to apply it freely over all the affected portions of the skin. She brought the baby back in a few days, and stated that, in a few hours after the application of the ointment, the incrustation was removed with perfect ease. On examining the baby, only a reddened condition of the skin was found, it being soft and velvety. Over the entire surface the dilated openings of the sebaceous glands were plainly visible, and a condition was observed which had not been noticed at the first examination. There was a hypertrichosis situated over almost the entire body, but most marked upon the lower extremities. These were thickly covered by a growth of hair, light in color, of about the same individual size as the hair upon the patient's scalp, and of an average length of nearly one third of an inch, some being as long as one-half inch, others shorter. On the upper extremities the condition was not developed to so marked a degree, and on the body there was only a more decided hairy development than would normally be the case. The hair on the body was of an average length of about one-fifth of an inch. On the face the hair was likewise somewhat increased, but on the scalp it was about normal. It was light in color, soft and silky. The mother could give no definite information as to whether this condition had existed since birth, or whether it had developed subsequently to it, as she had never given any particular attention to it.

The removal of the scales ensued with great rapidity. The surface left without ointment was covered in a few hours with a coating of sebum, and at the end of twenty-four hours small brown scales could be detached. A regular line of treatment was instituted, but beyond keeping the scales away it has produced little benefit. A renewal of the incrustation ensued as soon as treatment was in any way omitted.

The affection presented by this little patient is one of considerable interest, both on account of its rarity and from its being associated with a hypertrichosis. It is rather difficult to say definitely to what extent this hypertrichosis was natural, or whether it was partly associated with a hypertrichosis irritativa. The mother had not

paid sufficient attention to it to state how long it had been present, and necessarily the hairs could give no clue. Their greatly increased length, however, on those portions of the body where the incrustation was most marked would seem to indicate that this was due to irritation, but then a condition of hirsuteness, though less marked, was also present on those parts not yet invaded by the process. The growth of hair, on the other hand, could scarcely be that ofttimes seen at birth and persisting for a few weeks at the utmost afterward, since they would not have remained unshed up to the age of seven months, and neither could they have been retained there by the incrustation. This latter was not continuous from the beginning of the affection, but it was at times cast off of its own accord; and, moreover, they should have come away with the incrustation when it was removed by the application of the ointment, if this had been the case. But it was not. The hairs, when noticed at the time of the second visit, were all firmly attached to their papillæ, requiring the usual amount of force to remove them. The most probable explanation of the condition, to me, was that a degree of true hypertrichosis did exist from the beginning, and on those parts subjected a long time to the irritation caused by the presence of the incrustation a condition of hypertrichosis irritativa ensued, and we thus found the hairs longer on those parts than on those not yet implicated in the process. In view of this hypertrichosis, the question was brought up as to what possible connection there could be between the two processes, if any. Unfortunately, no microscopical examination of the tissue was possible, and little aid is obtainable from the literature of hypertrichosis, it being entirely taken up with the clinical features and the distribution of the hairs, no record of a microscopical examination of the sebaceous glands being recorded. It is, however, perfectly presumable, that if, on those parts of the body normally occupied by lanugo hairs with rudimentary glands attached and a comparatively small number of fully-developed sebaceous glands, a growth of hair is found approximating and corresponding to that of, for instance, the scalp, there will be an accompanying development of the sebaceous glands. Naturally, I refer here to the condition known as hypertrichosis adnata, and not to hypertrichosis produced only by irritation. The very large amount of sebum poured out upon the skin of this little patient would be partly accounted for should this development of the sebaceous glands be present, but in the absence of a microscopical examination any theory must remain only suppositious. The association of these two conditions is curious and interesting, but what interdependence, if any, existed between them, is of course under the circumstances not capable of being proved. A further peculiar symptom in the case is the appearance of the erythematous patches and plaques preceding the accumulation of the sebaceous matter. In seborrheic affections in general the skin affected by the process is either unchanged in appearance, or only secondarily does it become reddened and congested.

But, in this patient, the first symptoms presented consisted of circumscribed plaques of diffuse redness, upon which was subsequently developed the sebaceous incrustation. The appearance of these plaques is certainly curious, and suggests a vaso-motor disturbance; that by means of some cause a dilatation of the blood-vessels through the action of the vaso-dilator nerves occurred. These areas of congestion always preceded the increased sebaceous secretion, and the accumulation of sebum on the skin was entirely limited to them, the remaining portions of the cutaneous surface being entirely free. Moreover, from the beginning of the affection, as the area of congestion proceeded from its starting-point, the dorsum of the feet, and encroached upward upon the lower extremity, so also did the sebaceous incrustation keep pace with this encroachment, but at no time did any seborrheic disturbance precede the erythematous condition. That there was a causal connection between the congestion and the excessive secretion of sebum, is undoubtedly true. An excess of nutrition being supplied to the glands through the great increase in the amount of blood going to them, they would be stimulated to great activity, with the result of a largely increased secretion of sebaceous matter; furthermore, this abnormal activity would also show itself in the rapid production of new epithelial cells, and the equally rapid casting off of the old ones. Many of these latter would thus be desquamated without having undergone complete fatty degeneration, and would pass out through the ducts, together with the rest of the products of the glands. Having arrived upon the surface, they became there horny in character through desiccation, and aided greatly in forming the incrustation. This seems to me to be the part played by the congestion in causing, or, at least, in greatly aiding the hypersecretion of the sebum, but when the cause of the congestion is sought, there is nothing from which any conclusion can be drawn. Our knowledge as yet of neuropathy in connection with affections of the skin is very limited, and few proved and accepted facts in regard to it are recorded. This patient showed certainly no symptoms referable to any disturbance of innervation, and the areas of congestion, though on their first appearance, and during their subsequent development, they were for the most part symmetrical, yet were not entirely so. Subjectively, there was nothing to deduct from; yet, from the objective symptoms, it is presumable that some nervous disturbance existed, but what was its cause, or how it originated, it is scarcely possible to say.

Clinical Department

CIRRHOSIS OF THE LIVER IN CHILDREN.

Dr. Wesley M. Carpenter, of this city, writes that the case reported by Dr. Marsh, of Oswego Falls, N. Y., in The Medical Record for December 19, 1885, recalls the fact that those who have opportunity to make autopsies in large numbers, occasionally find cirrhosis of the liver in young subjects. He has in his collection at the Laboratory of Biology and Pathology, University Medical College, specimens from children four and seven years of age, in which the lesion exists to a remarkable degree, giving to the organ a nodular appearance, and exhibiting, with the microscope, broad bands of interstitial growth.

In this class of cases, it is important, in studying the etiology, to ascertain the facts concerning the existence of syphilis. Moreover, it is not impossible that, in some instances, alcohol, even at the early age of two and a half years, may be allowed to exert its influence on the tissues through the agency of nurses.

ABNORMAL MOTILITY OF TONGUE—ENLARGED UVULA.

Dr. John Winslow, of Ithaca, N. Y., writes: "The ability to explore the naso-pharyngeal space with the tip of the tongue is probably not so very rare. To the cases lately reported in The Record, I can add that of Isaac N. Van O——, who called upon me April 16, 1879, in great distress of mind, since he had discovered a hole in each side of his throat behind the palate. To my questions he replied that he felt the holes with his tongue, as he would show me; and he at once placed the tip of that organ in the orifice of either Eustachian tube. This was proved by introducing the Eustachian catheter, which he could feel and dislodge with the tongue. This patient could also move his ears to a quite unusual extent.

"My surprise at the disappearance of the tongue be-

hind the velum in this case was hardly greater than at the comical annoyance of a colored man who consulted me for a bad habit he had of swallowing his palate! I expressed doubt, when he indignantly said he would vomit it up before me, and, true enough, he threw forward upon his tongue a uvula nearly three inches long, with a bulbous extremity about three-fourths of an inch broad. The dimensions were increased at the time by œdema attendant upon an acute faucitis. Of course, he could not keep the mass in his mouth, and so packed it away in the lower pharynx; and equally of course he was speedily relieved."

ALARMING SYMPTOMS FOLLOWING VACCINATION.

Dr. F. L. Putt, of Middlebury, Ind., writes that he was much interested in the report of two cases by Dr. White, under the title "What Is It?" in The Medical Record of December 12, 1885, but regrets that an inquiry concerning the virus used was not made. He says that in 1881 he noticed in several of his cases of vaccination a decided tendency to stupor, and, at the same time, a slight suppression of urine, and, quite frequently, retention. The patients complained of a difficulty in commencing micturition, and the urine on cooling deposited a copious sediment. The older patients stated that they noticed this as soon as the vesicles began to form on the arm, and that it continued until the crust became detached. There was also tenderness on pressure over the kidneys. Quinine, chlorate, and nitrate of potassium, bicarbonate of sodium, camphor, and sometimes gelsemium and cannabis indica, were given in varying proportions. The patients all recovered under this treatment. All of these cases occurred in the same neighborhood, and were the result of one day's vaccination. On inquiring concerning the virus of the physician from whom it was obtained, it was learned that it was procured from a foundling asylum. This same physician had more bad results than all the others in the town. Dr. Putt considered the trouble to be an irritation of the kidneys from blood-poisoning.

DISLOCATION OF THE UNGUAL PHALANX OF THE THUMB.

Dr. R. B. Jessup, Jr., of Vincennes, Ind., reports the following rare case: "Mr. Hoké, a Frenchman, sixty-five years of age, residing three miles south of town, fell into his cellar on November 9, 1885, sustaining various bruises on the body and head. He was well enough on the third day to come to town to have his thumb examined. In his fall he injured it, and as seen by me, there was considerable swelling, and the second (ungual) phalanx was immovably fixed in a position almost at a right angle to the line of the first phalanx. Careful examination revealed the articular surface of the second phalanx looking backward, and the phalanx displaced in the same direction. The reduction was simple. Flexion was forcibly made, and at the same time pressure in a forward direction was exerted on the articular surface of the phalanx. This was seen by another surgeon, and was undoubtedly a case of simple dislocation of the second (ungual) phalanx backward on the first phalanx."

A REMARKABLE CONGENITAL DEFORMITY.

Dr. Blair D. Taylor, Captain and Assistant Surgeon U.S.A., of Little Rock Barracks, Ark., writes that he was called to see a girl seven years old who presented the following conditions: "There was complete atrophy of the left scapular muscles, with the single exception of the deltoid, which retained sufficient power to raise the arm about two inches. The entire upper extremity on the same side was nothing more than a cylinder about one inch in diameter, consisting solely of integument and bone. The elbow was bent at a right angle, and anchylosed, and the extremity of the forearm was clubbed, and presented some faint traces of a division into a thumb and fingers, the latter being consolidated. Both pectoral muscles on this side, the latissimus dorsi, serratus magnus, trapezius, rhomboids, and all the other muscles of the arm, forearm, and hand, were completely shrunken and useless. On the front of the shoulder, just over the coracoid process, was a deep scar, about the size of a nickel five-cent piece, and just above the spine of the scapula were three deep scars, about half as large as the other. Both parents had dark eyes and complexions, but the child had a gray eye on the left side, and a dark-brown one on the right. The left side of the head, face, and neck was pale, and never became flushed or moistened with perspiration during exercise. On the right side, the complexion was ruddy, and perspiration was free, and increased by exertion. The child complained of frequent neuralgic pains in the milk-teeth of the left side of the mouth, although they were as perfect in appearance as those on the other side. The sight of each eye was equally good, and there was no atrophy or paralysis of the facial muscles, or of the sterno-cleido-mastoids. In every other respect the girl was perfectly developed, and she was unusually active and intelligent for her age. Examination of the left lung showed no abnormality, except a lack of expansion on that side from atrophy of the serratus magnus. The heart and other internal organs were healthy as far as could be determined. The occasion of the visit at this time was for advice concerning an indolent ulcer over the left elbow, which had existed almost constantly from birth, healing up at intervals, and reappearing upon the receipt of any slight injury. The existence of this ulcer was easily explained by the feebleness of the circulation in the left arm." Dr. Taylor is inclined to attribute this arrest of development to the influence of maternal impressions. He learned that the mother, when two months pregnant with this, the first child, while passing through a neighbor's yard, was suddenly attacked by a large and fierce dog, who sprung up, attempting to seize her by the left shoulder. The woman threw up her left hand to the same shoulder, and disengaged her cloak, leaving it in the animal's jaws, escaping herself without any physical injury. To the fright and lasting impression which this incident left upon her mind, the mother attributed her child's deformity. Both parents are healthy, and two children born subsequently are physically perfect. When the child was born the stump of the hand was touching the left acromion process, in exactly the position which the mother's arm was while she was disengaging her cloak, but by subsequent manipulation the forearm was brought down to its present position at a right angle to the arm. The scars on the shoulder resembled such as would have been produced on the mother had the dog succeeded in his attempt to imprint his teeth in her shoulder.

A CASE OF PNEUMOTHORAX.

Dr. Benjamin R. Symonds, of Beverly, Mass., reports the following interesting case:

On July 15, 1885, H. C——, a boiler-maker by trade, presented himself at the Out-Patient Department of the Rhode Island Hospital for treatment. The patient was a man of forty years of age, well nourished, muscular, and up to the present trouble had "never had a day's sickness."

July 11th, four days before he sought the advice of a physician, he was at work as usual. Suddenly, "while inside a fire-box," "riveting stay-bolts," he "felt all filled up with air." He stopped work, and came outside, thinking the air would make him feel better. He obtained no relief, however, and very soon quit work and went home.

Severe pain in the left chest and back developed, for which he applied turpentine, but with no relief. He soon began to suffer from a slight cough, but raised nothing; found that he was unable to lie down, and lost his appetite and strength.

This is the history he gave, and his symptoms had remained about the same. We will now proceed to examine into the physical signs which immediately throw considerable light on the case.

After removing the clothes from the upper portion of the body, inspection showed the chest to be rather one-sided, the left side being much more prominent than the right; there was considerable fulness above the left clavicle, the intercostal spaces were bulging, and during respiration the right side of the chest appeared to do about all the work.

Chest measured thirty-seven inches; thoroughly expanded, thirty-seven and a half inches; fully contracted, thirty-five inches. The left side of the chest measured the most, but the power of expansion, however, was found to be in the right side.

Percussion showed exaggerated resonance over the whole of the left side, and where the muscular walls were thinnest this resonance was tympanitic. The cardiac dulness showed the heart to be displaced to the right.

Auscultation revealed increased respiratory murmur on the right side, no respiration at all anywhere on the left side. But all over the left chest could be heard metallic tinkling.

The suddenness of the attack and the attendant symptoms, together with the physical examination, seemed to me to point to a rupture of an air-vesicle and a filling up of the left pleural cavity with air.

At the end of three weeks' time the patient had regained his appetite, but could not exert himself without getting all tired out. The examination of the chest still showed that the pleural cavity was filled with air. But in six weeks I noticed a change; there seemed to be a faint respiratory murmur over the left side anteriorly, and this gradually increased in area until, in two months, the chest appeared to be in a normal condition, and the patient had gone back to his employment.

Progress of Medical Science.

Morbid Arterial Tension.—This subject, which may well claim the serious attention of the practitioner, was ably handled by Dr. Goodhart, in "The Bradshawe Lecture," for 1885. In the *London Medical Record*, November 15, 1885, a *résumé* appears, which sets forth the points of chief interest in the questions derived from the association of morbid arterial tension with Bright's disease. Bright noticed the hypertrophy of the left ventricle that occurs in chronic renal disease, and attributed it to the impurity of the blood, and to the extra work thus thrown upon the heart, in consequence of the refusal of the tissues to allow a free passage to a substance of which they disapproved. Dr. George Johnson at one time held much the same view, but abandoned it for what is now well known as the stopcock theory; this supposes that the function of the muscular coat of the arterioles is a controlling one; and that, when blood is ill-adapted to the tissues, control will be increased, and the blood shut off more or less from the tissues. Obstruction then must necessarily be created behind, and throw increased work upon the heart, and thus account for the hypertrophy of the left ventricle. As an athlete increases the size of muscles which are constantly used, so does the muscular tissue of the vessels and heart become increased by this extra work that is put upon them. The author and Dr. Dickinson are, however, of the opinion that the function of the muscular coat of the arteries is not a retarding or controlling one, as insisted upon by Dr. Johnson, but rather a propelling one. To demonstrate this theory, the action of digitalis is brought forward. Digitalis is said to increase the action of the muscular wall of the heart on the one hand, of the arteries on the other; now, if the muscular coat of the arterioles control and retard the circulation, the undoubted diuretic action of digitalis is not easy to explain. As regards the existence or not of spasm, Dr. Goodhart states that there can be no muscle, and no physiological muscular action, without the risk of the frequent exhibition of morbid muscular action, or spasm; and the assumption of some such spasm in the muscular tissues of the arteries is very agreeable in explaining many of the phenomena of Bright's disease; for instance, the headache and renal asthma are often much relieved by nitrite of amyl and nitro-glycerine, both drugs unquestionably acting by relaxing spasm and promoting dilatation of the peripheral vessels. The subject next expands in two directions: on the one hand by the hypothesis that chronic Bright's disease is an arterio-capillary fibrosis, or generalized tissue-change, and, on the other hand, by the use of the sphygmograph. Taking the arterio-capillary fibrosis theory first, the author quotes from the paper of Sir William Gull and Dr. Sutton, in which they say, "Old age is not an entity, but a set of conditions predisposing to that state which is called chronic Bright's disease." Old age is no matter of years and averages, but the running down of a spring set for an individual. It comes at times even to children; and although chronic Bright's disease is in many cases associated with renal disease, it is not essentially a matter of organs; the generalized change in the tissues of the whole body is the essential, and to some this comes not by kidney chiefly, but by lung chiefly, by brain, by heart, etc. This idea is a suggestive one, and is largely true, but it derives its strength less from the labors of the histologist than from the intuition of experience; to base it upon the non-existence or unimportance of muscular hypertrophy in the arterioles, and to ascribe the thickening which exists, to an essential hyalin-fibroid degeneration, is, in the opinion of Dr. Goodhart, a mistake. There are, no doubt, groups of cases in which the disease in the kidneys is certainly the cause of the changes in the heart and arteries; for instance, in a large proportion of cases of chronic parenchymatous nephritis the heart and arteries are hypertrophied, and this without doubt is due to the kidneys. Again, in some cases, the failure of health and of nutrition will not unfrequently combine so to reduce the arterial tension, as to deprive the circulatory system of any excuse to hypertrophy. These cases are more dangerous than those of granular kidney, because the left ventricle has more tendency to dilate, and thus to relieve the excessive tension, so that the death of the patient often forestalls the hypertrophy of the heart and arterioles. The author puts forward thef ollowing statement with reference to these cases of renal disease. "In proportion as the renal disease is sudden and severe, so is the risk of dilatation of the heart. The more insidious it is, the more likely is the cardiac hypertrophy to be present in greatest perfection." Another important point to bear in mind is that, while granular kidney often terminates in cerebral hemorrhage, the subject of chronic parenchymatous nephritis rarely dies by that means (in lardaceous disease cerebral hemorrhage is still rarer). At first sight, this would seem to favor the view that the disease of the vessels is a peculiar one, and independent of the nephritis; but it is obvious that dilatation of the heart is unfavorable to the occurrence of apoplexy; it relaxes the tension at the centre which would otherwise be put on at the periphery, and death comes about by cardiac failure, and not by peripheral hemorrhage. Concerning the pathology of the arterial changes, and the excess of the hyalin-fibroid material which is observed, together with the atrophy of the muscular coat in the arteries, the author explains his views on the following grounds. The general demand for labor is physiologically responded to by general hypertrophy of all the tissues of the arterial coats, so that not only is there

hypertrophy of the muscular coat, but also of the connective-tissue materials of the arterial walls. When this is once established, and the conditions for obtaining supplies are prohibited in any way, then the least organized tissues seem to grow at the expense of—or, as it is termed, by "sponging" upon—the more highly organized structures; and thus in a case of chronic renal disease of the tissues and vessels it is possible to find vessels conspicuous for their increase of muscular tissue in one part, and in another conspicuous for the increase of their hyalin-fibroid structures. There is another aspect of the question, which provides ground for belief in the existence of diffused degeneration before any serious mischief can be detected in the kidneys. Ever since the time of Bright it has been felt that the discovery of albumen in a patient's urine is a late and rough test of disease, and during the last few years several observers have discovered what they consider early manifestations of the disease; but it was Mahomed who taught us more than any one, by his observations with the sphygmograph, how to detect the pulse of high tension. In one of Mahomed's most valuable papers on this subject ("Transactions of the Royal Medical and Chirurgical Society," 1874) it was shown precisely that morbid conditions of the pulse (high tension) precede any evidence of disease in the kidney. Mahomed draws the conclusion from a number of observations, that the vascular condition is the cause of the albuminuria, and not the converse, as had been generally supposed. As early as 1849 Dr. Walshe stated that Bright's disease was not renal, but primarily a blood-disease. Dr. Goodhart next alludes to what he considers the strongest evidence in favor of the generalized nature of the changes which include chronic Bright's disease. It forms the subject of some of Mahomed's latest work in a paper on "Chronic Bright's Disease without Albuminuria" ("Guy's Hospital Reports," Series 3, vol. xxv.). Dr. Goodhart, however, rejects this nomenclature; and says that Bright's disease, if it means anything, means nephritis, and suggests that some such title as arterio-capillary fibrosis should be used to include all these cases.

Renal Lesions in Hereditary Syphilis.—Dr. E. Marchiafava thus describes the lesions found by him in the kidney in two cases of hereditary syphilis (*Rivista Clinica*, No. 10. 1885). The organs were of normal size, but the cortical substance was of a grayish color and dotted with minute whitish nodules, corresponding to the glomeruli. Under the microscope the lesions were seen to proceed from a diffuse arteritis of the glomerular and afferent vessels. The arteries were contracted, and finally obliterated, and became converted into a hyaline mass. The vascular loops of the glomeruli were thus destroyed, as was also at a later period the epithelium of the convoluted tubules, which derives its nourishment from the afferent vessels.

Eruptions Following the Use of Quinine.—In a recent thesis, Dr. Levassor presents a study of the different forms of eruption which may be caused by the ingestion of sulphate of quinine (*Archives Médicales Belges*, November, 1885). The eruption, which is of very rare occurrence, may be observed under four different forms: scarlatinal, rubeolar, papulo-erythematous, and purpuric. The first variety may present so close a resemblance to scarlatina as to render a differential diagnosis a matter of great difficulty. In a case seen by Dr. Levassor there were high fever, a rapid pulse, cephalalgia, and general malaise. The eruption appeared soon after and involved not only the integument but also the mucous membrane of the fauces, but was not accompanied with any pain or swelling of the tonsils. The deception was rendered complete by the occurrence of desquamation at the end of four days. The true nature of the eruption was recognized only upon its recurrence some time later after a second dose of quinine. The rubeolar form is more frequent than the preceding. It is manifested by the sudden appearance of an eruption of small, rose-colored spots, spread over the whole body, and not raised above the surrounding integument. These disappear rapidly and are followed by desquamation. The erythematous variety differs from that just described in that the red spots, project above the surface, resembling very closely a papular erythema. The purpuric form is very rare. There are a few small, lightly ecchymotic spots localized in certain regions of the body, which appear and disappear with great rapidity. These different eruptions may be caused by a very small dose of quinine, and are due to a real idiosyncrasy of the patient. They are without danger, and in case of their appearance, if the quinine is really necessary, it may be continued without regard being had to the cutaneous manifestations.

The Nocturnal Cough of Children.—It not infrequently happens that children are waked suddenly from quiet slumber by a violent, and sometimes convulsive, cough. This has been ascribed by McCoy to reflex irritation from accumulation of mucus within the nasal cavities. During the day the mucus flows away, but in the night it collects upon the sensitive areas in the nasal fossæ and excites a cough. Dr. Gonzalez Alvarez thinks this theory untenable, except in a few rare instances, and attributes the cough to laryngeal irritation. He says that the saliva and buccal mucus accumulate in considerable quantities, especially when there is stomatitis or gingivitis from dentition. Most of this is removed by the acts of deglutition which take place during sleep, but some does not so escape, but trickles into the posterior commissure of the larynx. He states that this cough occurs very frequently during the period of dentition, even when there is no nasal catarrh, a fact which leads him to reject the theory of nasal reflex irritation. The treatment of this nocturnal cough consists in diminishing the secretion by means of chlorate of potassium. A teaspoonful of a two per cent. solution is given every hour or two hours during the day, and at bedtime.—*Revue Bibliographique des Sciences Médicales*, November 22, 1885.

Resection of the Knee in Children.—The following are the conclusions of Dr. Rivera y Sanz, in an article on this subject published in the *Archivos de Medicina y Cirurgia de los Miños*, Nos. 1, 2, 6, 7, and 8, 1885: 1. The value of active intervention by means of resection of the joint is indisputable. 2. Resection should be preferred to amputation when the affection is exclusively local; but should, of course, be reserved for those cases in which other more conservative measures have been shown to be ineffectual. 3. If osteitis of the knee coexist with disease of the internal organs, resection is contra-indicated. The question of amputation in such cases is to be determined by the degree and character of the visceral complication. It has never been proven that the operation may give rise to the appearance of new foci of tubercular disease in the internal organs. When such metastases occur they are due to the fact that the operation was incomplete, and are, therefore, the result of auto-inoculation.

Fecal Umbilical Fistula.—Dr. Talini relates the case of a boy, nine years old, who had suffered for about two months from what the attending physician regarded as typhoid fever. Growing better, he was sent to the country, but while there was taken again with fever, abdominal pains, and diarrhœa. In a short time a red, tense, painful swelling appeared at the umbilicus, and opening spontaneously, a fistula communicating with the intestine was formed. The child became more and more emaciated and weak, and finally died. The autopsy revealed the existence of acute miliary tuberculosis of the pleura and peritoneum and also the presence of a large cavity at the apex of the left lung. The fistula had arisen from perforation of the transverse colon, which was adherent to the abdominal parietes, from the corrosion of a tubercular ulcer.—*Lo Sperimentale*, November, 1885.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 16, 1886.

THE DANGER TO THE KIDNEYS IN THE USE OF MERCURY.

Two years ago we called attention to a new non-mercurial treatment for syphilis, devised by Dr. Güntz, of Dresden. This treatment consisted, so far as drugs went, in the administration of "chrom-water," a watery solution of chromic salts.

We believe that the chrom-water treatment of syphilis has not gained the confidence of therapeutists. Yet Dr. Güntz does not lose faith in it, and in a recent article in *Memorabilien* he puts forth a new reason for adopting it. This reason is, in brief, that in a certain large per cent. of syphilitics the use of mercury is dangerous, because it is liable to bring on or aggravate renal disease.

Dr. Güntz collects a number of records, showing that in the systematic treatment of syphilis by mercurialization deaths reaching to 3.5 per cent. have occurred; these deaths, he believes, being due, in part at least, to the action of the mercury on the kidneys.

Dr. Güntz collects also considerable evidence from various observers, showing that the continuous administration of mercury may cause albuminuria. On this point he will meet no opposition, since it is quite generally admitted that such accidents may happen, and that albumen not very rarely appears in the urine in hydrargyrosis.

But, aside from this, Güntz argues that mercury is a dangerous drug to use when Bright's disease is already present, and in phthisis. In either of these disorders the production of mercurialism may result in grave accidents, or even death.

Now, according to Bamberger's autopsical records, there were found in 19,000 necropsies 2,430 cases of Morbus Brightii, besides a very great number of other forms of renal disease. Spiess is quoted as saying that among 220 post-mortems on syphilitics, made at the Charité, over one-half (147) had renal disease.

The large proportion of kidney disease among syphilitics is accounted for on three grounds: 1, The ordinarily considerable per cent. of Bright's disease; 2, the predisposition to renal disease in the eruptive period of syphilis (*vide* Dreyfuss-Brisac, Colvis, and Lesser); 3, the general use of the mercurial treatment of syphilis.

According to Güntz, twenty per cent. of adult men are syphilitics, twelve per cent. have Bright's disease, and therefore the probabilities are that among 20 syphilitics 2 will have renal disease. In the same way, among 100 men 20 are phthisical, so that among 20 syphilitics 4 would probably have some lung affection, contraindicating mercurialization.

Still further, our author indorses the opinion of Von Sigmund, that two-fifths, or forty per cent., of cases of syphilis are cured spontaneously or without the help of mercury.

A table can therefore be constructed, showing the proportion of syphilitics that are wrongly or needlessly treated by mercurials, as follows: ten per cent. having kidney disease; twenty per cent. having tuberculosis; forty per cent. who will get well anyway, or under other than mercurial treatment; total, seventy per cent.

This leaves only thirty per cent. of syphilitics to receive the benefits of mercury. The figures given by Güntz, whatever their significance in Germany, will have to be changed somewhat for our climate.

For example, the proportion of Bright's disease among adult males is much less than ten per cent. Among 19,000 deaths in this city in persons between the ages of fifteen and sixty, there were only 670 deaths from nephritic diseases, or about three per cent. The proportion of deaths from phthisis among adults is also less than twenty per cent., ranging from twelve to eighteen per cent. Syphilis does not affect one in every five adult male Americans. This high proportion is perhaps reached among certain classes living in large cities or manufacturing towns, but the general testimony of country physicians everywhere is that syphilis is a rather rare disease, and only met with a few times yearly by those in active practice.

The force of Dr. Güntz's figures, however, is not destroyed by the fact that they do not apply with strictness to our country. He has brought out two important points, viz., that there is always need of caution and watchfulness in using mercury continuously, and that many cases of syphilis can be treated successfully without mercury.

A NEW ERA IN THE TREATMENT OF INTERNAL DISEASES.

WE are told by Dr. Albert Reibmeyer, in *Memorabilien*, that a new era has been created in medical treatment by the labors of Körner and Oertel. "What Lister has done for surgery, Oertel has done for internal medicine." The rational basis for modern surgery is cleanliness and antisepsis; in internal medicine it is "regulation of the blood-pressure." Our medical fathers used to attempt this by exhausting venesections, nauseants, purges, and mercurials; later, we tried to get along by tonic measures which would drive on or tone up the laboring heart, or by stimulating the feebly-acting glands and absorbents. Some years ago Körner advocated the dry method of treating acute exudative processes, and even of serous transudations. In pleuritic effusions he cut down the amount of water for a time; he then gave small but frequent doses of chloride of sodium. The thickened blood, enriched with salt, attracted the exuded fluid, and absorption rapidly took place. Thoracentesis, we are told, was never necessary. Dropsical accumulations were removed by the same plan. Körner applied his principle (*Memorabilien*, 1861) in the treatment of acute Bright's disease. Of late Oertel has independently taken up and recommended the same kind of measures. Instead of

sweating and purging the patient while at the same time large amounts of water are given to make up for that lost, he simply cuts down the supply. In this way the blood-volume and pressure are lessened, and the kidneys are rested. We have already referred to Oertel's "dry method" in the treatment of fatty and otherwise inadequate hearts. He aims here, also, by diminishing the volume of blood to lessen the work of the heart.

In the *Medical and Surgical Reporter* of November 21, 1885, Dr. L. Casper reports a case in which he successfully applied Oertel's principle. The patient was a man forty-two years of age, who was apparently in the last stages of cardiac and renal dropsy. He was a small man, with a thorax deformed by kyphosis, "evidently causing great contraction of the organs of the chest." The heart was much enlarged, and its beat scarcely perceptible. Dr. Casper does not seem to have been able to make out any valvular lesion. The urine contained a large quantity of albumen. His legs were very œdematous. He was prescribed the following diet:

Fluids.—Six A.M.: Coffee or milk, ca. 125.0 grammes. Noon: 125.0 grammes wine. Evening: 250 grammes wine.

Meats.—Six A.M.: One egg, one roll (ca. 55.0 grammes). Nine A.M.: 80.0 to 100.3 grammes meat, one roll. Noon: 125.0 grammes meat, a little vegetables (green, if possible). Evening: 250.0 grammes wine, 125.0 grammes meat, one egg, a little bread.

Only in case of extraordinary thirst being felt could 125.0 grammes of light beer be drunk, additionally, during the evening.

The amount of liquid allowed was thus only from one pint to a pint and a quarter daily. Under this regimen he lost in weight six kilogrammes (about thirteen pounds) in five and a half weeks, his original weight being one hundred and forty pounds. In the latter period he was given four grammes of salicylic acid daily, he salicylic acid being given instead of pilocarpin, which Oertel recommends.

With the decrease in weight the patient's strength increased, until at length he was able, although with difficulty, to take walks. The difficulty in breathing became lessened, so that after two weeks the patient could sleep a few hours in bed. The œdema disappeared. The abdomen became softer, so that the liver could be felt. The quantity of albumen deposited in the urine remained unchanged for a long while. The patient, in fine, was taken from death's door and put in a comfortable state of health, and enabled to attend to business.

In another case, reported by Dr. Casper, of a similar character, the following diet was prescribed:

Fluids.—Morning: Tea, 100.0 grammes; milk, 25.0 grammes; sugar, 5.0 grammes. Noon, one hour before eating, 50.0 grammes of sherry wine. Afternoon: Coffee, 100.0 grammes; milk, 25.0 grammes; sugar, 5.0 grammes; Evening: Wine, 100.0 grammes; water, 60.0 to 100.0 grammes.

Meats.—Morning: Roll, 35.0 grammes; raw meat, chopped finely, 80.0 grammes; two soft-boiled eggs. Noon: Meat, 150.0 grammes; vegetables, 100.0 grammes; fruit, 50.0 grammes. Afternoon: One egg, soft-boiled. Evening: Two eggs, broiled meat (cold), 80.0 grammes; roll (no butter, if possible), 50.0 grammes.

Here a cure apparently resulted. These cases are not very accurately reported, especially as regards the physical examination. They serve to illustrate, however, the method of dietetic treatment.

THE TREATMENT OF CHRONIC PLEURISY.

It is a well-known clinical fact that in diseases attended with the exudation of inflammatory products, the amount of the chlorides in the urine is diminished, and even entirely suppressed. This is notably the case in pleurisy and pneumonia. Indeed, some writers recommend a daily examination of the urine in all cases of the latter disease, and claim that a return of the chlorides to their normal amount argues a favorable prognosis, even though signs and symptoms may not show that the crisis has been passed. Acting upon the above theory, a mode of treating pleurisy (sero-fibrinous) was adopted some twenty years ago by Körner in Germany, and some definite results seem to have been reached. The method, in brief, consists in cutting down the fluid ingesta to a minimum and giving rapidly-absorbed salines. Common table-salt is found to fulfil this indication perfectly.

To make practical application of this method, a careful measurement is made of the fluid ingesta and of the daily amount of urine excreted. The former are then cut down (if necessary) till the daily amount of urine equals about two-thirds of the fluids taken. This is about the proportion obtaining in good health. The advocates of this method lay great stress upon the ingesta-egesta relation in all circulatory and respiratory diseases.

In exudative pleurisy, the daily quantity of urine is generally small. The amount of fluid taken is therefore restricted till the above-named ratio is reached. No warm drinks are allowed, and only just enough cold water to quench thirst. The salt is then given in moderate amount, preferably in capsules or wafers, to avoid the sensation of thirst which would result from its contact with the mucous membranes of the mouth and throat. The idea is that the rapid absorption of the saline is followed by diffusion into the exudation, with corresponding absorption of fluid, which is then excreted by the kidneys.

It is no new idea to cut off all fluids in cases of disease attended by serous exudation. It is claimed that the above method of restricted allowance is followed by just as good results as where drink is absolutely prohibited; and of course it is much less annoying to the patients. Glax has reported a series of twenty-five cases of serous pleurisy extending over a period of three and a half years. In thirteen cases the fluid did not reach above the inferior angle of the scapula. These all did remarkably well. In the remaining cases the chest was nearly full of fluid on one side. Of this latter group the average period of illness was twenty-two days. The mean period in the whole twenty-five cases was considerably less. The average duration in the "total abstinence" method has been given as twenty-eight days.

In comparison with these figures, it may be stated that the mean duration of illness in cases treated by the usual tapping and diuretics is given as over forty days. The advocates of the restrictive-saline method do not regard tapping as indicated, unless there be serious dyspnœa from the presence of fluid. At least three weeks should be al-

lowed under other circumstances before tapping is resorted to. They point to the well-known fact that paracentesis of the chest, and even merely repeated trial-punctures, may change the character of the exudation from serous to purulent. This risk has of course been greatly reduced under present antiseptic methods. It is never entirely wanting. The method outlined is certainly an easy one to follow. The slow course of serous pleurisy is but too well known. The plan suggested is well worth a trial.

THE VALUE OF TRAINED NURSES.

The Lancet has been taking the rather curious ground that "trained nurses" are hardly necessary adjuncts of medical work, even if they may not be classed absolutely as superfluous and troublesome. "What nurses are trained to do could be done as well by ordinary servants if the practitioners would and could give precise instruction as to details. The knowledge a trained nurse possesses—the very utmost she can acquire—must be simply so much quackery, in so far as it extends beyond the mere womanly qualification of ministering gently to the sick and obediently carrying into effect a careful practitioner's instructions. Unhappily, female nurses are actually allowed to pass catheters and give hypodermic injections."

That trained nurses are a most useful and almost necessary help to the physician is part of the medical creed in this section of the country. We doubt if a medical man can be found in this city who does not believe in their utility.

It must be confessed, however, that the thing is being a little overdone, and there is sure to be before long something o a reaction. A trained nurse who never should have been a nurse is capable of doing vastly more harm than even the ancient Sarah Gamps, and there are already a great many of these trained women, with enamelled badges, who are untrustworthy, gossipy, mischievous creatures, demanding large pay for ridiculously incompetent service. The socia status of the trained nurse also often makes trouble. We are getting now a class of women who are so much trained that they refuse to do a single item of domestic labor not strictly in their line. They must work on embroidery in the parlor evenings, and if not quite good enough to sit with the family, they are much too good to sit with other servants.

The whole trouble comes from the almost inevitable necessity of training, as nurses, women utterly unfit for such a calling.

These drawbacks, however, do not prevent us from recognizing the extreme value of trained nurses; and *The Lancet's* position is so truly mediæval as to be unworthy of discussion.

GENEROUS CONDUCT TOWARD A BROTHER PHYSICIAN.

It is a great satisfaction to learn of the generous and spirited manner in which the members of the English medical profession have taken up the cause of Dr. Bradley, of Chesterfield, England. In November, 1884, Dr. Bradley was convicted at the Leicester Assizes, before Lord Chief-Justice Coleridge, o an attempt to commit a criminal assault upon a patient, and was sentenced to two years' imprisonment with hard labor. It was believed by the medical profession that the evidence failed to support the charge, and that due weight had not been attached to the fact that the prosecutrix had from her childhood been subject to epileptic fits, and was therefore liable to delusions. The matter was taken up by the medical press, and influential memorials were presented to Sir William Harcourt, the late Home Secretary, urging an inquiry. It was, however, not until a change of government took place that the efforts proved successful. Sir Richard Cross made a careful investigation, and last July he recommended the release of Dr. Bradley, in whose behalf an appeal for subscriptions was commenced.

This resulted in collecting the sum of $2,000, which sum was publicly presented to him on the 11th ult., at a banquet given at Sheffield.

In making the presentation Mr. Jeffries, who had been largely interested in securing the subscriptions, said that petitions in Dr. Bradley's favor had been signed by no fewer than one thousand names, including those of nearly all the leading men in the districts from which they had been sent. In the neighborhood where Dr. Bradley was living when this calamity befell him, all his brother practitioners, without exception, signified their belief in his innocence, and aided in the efforts made in his favor. Mr. Jeffries continued: "In presenting this address to him, we raise our emphatic and indignant protest against the ready credence which the law has given, in his case, to a form of accusation very easy to make, but not always easy to disprove. We do this for our own sakes, because medical men in the daily discharge of their duties, which are often of a delicate character, are exposed, more than other men, to have such charges brought against them."

The action of our English confrères is highly creditable to their unselfishness and kindly feelings. It gives evidence of a spirit of pride in our calling, and of mutual helpfulness which cannot fail to react with benefit upon all connected with or interested in the case. Yet Dr. Bradley, we believe, got no more than was justly due him in the way of support from his medical brethren.

A NEW CARDIAC TONIC.

We have seen in the past few years a number of drugs brought forward as cardiac tonics, to take the place of digitalis. Some of these, as convallaria maialis, promised at first to be really formidable rivals, but they have all been shown, on a more extended trial, to fail in some point, and digitalis still holds the first rank in cardiac therapeutics. The latest claimant is sparteine, which, while not a newly discovered substance, has hitherto not been used as a medicament. It is an alkaloid of the *spartium scoparium*, or broom-tops, and was isolated by Stenhouse in 1850. The pure alkaloid occurs in the form of a liquid, very bitter in taste and insoluble in water, but the sulphate is crystallizable and readily soluble. Lauder Brunton ranges the drug with atropine and daturine as a paralyzer of the inhibitory ganglia of the heart, and experiments have been made with it by Mils, Fick, de Rymond and others, but the conclusions of different experimenters did not agree with each other, and nothing really was known as to the physiological and therapeutical properties of the drug.

In a recent communication to the Académie des

Sciences, M. Germain Sée detailed the results of a number of experiments made upon the human subject with sulphate of sparteine in doses of one and one-half grain. He found three characteristic and constant effects of the drug: The first and most important was a strengthening of the heart; the pulse, while previously almost imperceptible, became full and strong. The second was the almost immediate regulation of the irregular cardiac rhythm, in this respect surpassing that of any other known medicament. The third result was the acceleration of abnormally slow pulsations, resembling in this respect the action of belladonna. This triple action was observed within an hour or two after the administration of the first dose, and continued for three or four days after the sparteine had been discontinued. An improvement in the general strength and in respiration was also noticed, but there was no diuretic effect produced by the moderate dose employed.

M. Sée's conclusions were that sulphate of sparteine was indicated in all cases of yielding of the cardiac muscle, whether from alteration of its tissues or from extra work imposed upon it by an impediment to the circulation. And he asserts that it will speedily improve the character of the pulse when this is weak, irregular, and abnormally slow. We shall doubtless soon have reports from other experimenters with sparteine, and if they should be confirmatory, even in slight degree, of those of M. Sée, and should demonstrate also that the drug is a safe one to use, we shall have obtained a really valuable addition to our very short list of safe and certain cardiac tonics.

QUARANTINE AT THE PORT OF NEW YORK.

From 1880 to 1884, inclusive, nearly two millions of immigrants (1,986,278) entered the port of New York. The Health Officer has power to quarantine only yellow fever, cholera, small-pox, and typhus; yet in 1884 there were 154 cases of other contagious diseases, such as scarlatina, diphtheria, etc., introduced by immigrants.

In 1884, the total number of vessels entering the port and inspected by the Health Officer was 8,086. These carried 321,231 immigrants. Among them were found 184 cases of contagious and infectious diseases.

To accomplish all this work of inspection and quarantine, the State has a Port Health Officer and a Quarantine Commission of three. The Quarantine Commissioners have no very well-define duties, but they draw salaries to the amount of $7,500 annually, and their other expenses make a total of about $33,000 annually to the State.

The Health Officer is paid by fees, and gets, it is believed, from $50,000 to $75,000 yearly.

It is very desirable, from an economic point o view, that there should be some change in the present condition of things. The offices of the Quarantine Commissioners should be abolished, the fees should be lowered, and the Health Officer placed upon a salary, and made accountable to the State for his receipts. So far as efficiency in administration goes, the work of our port officers will bear criticism well. They have at times even done brilliant service in averting epidemics and keeping out disease; this is no excuse, however, for perpetrating a burdensome and extravagant method of maritime quarantine.

The real cause of its continued existence now is, that the "machine" must be run and the "boys" be looked after.

THE USE OF NAPHTHALIN IN CHRONIC DIARRHŒA AND IN TYPHOID FEVER.

Considerable has been written regarding the application of naphthalin in therapeutics. This is a substance derived from coal-tar, having a white, crystalline appearance, and a pungent odor, strongly suggestive of a gas factory. It was first used medicinally, according to Cagnoli, in 1842, as an expectorant, but did not gain the attention of physicians. In 1884, Dr. B. Testa studied its physiological properties. His conclusions were somewhat negative. He found that it was absorbed with difficulty, and that it had no effect upon normal temperatures, but that it reduced febrile temperature, diminished the excretion of urea, and did not cause albuminuria.

Dr. G. Fronmüller (*Memorabilien*, 1883, p. 257) used naphthalin in chronic bronchial catarrh and phthisis, with no very positive results.

Attention was first strongly called to the drug by Professor Rossbach, of Jena, who, at the Congress for Internal Medicine of 1884, strongly recommended it in disorders of the intestine. In chronic diarrhœa and dysentery, with or without ulcerations, Rossbach found naphthalin very efficient. He gave it in single doses of gr. ii. to gr. x. t.i.d., increasing this sometimes to daily doses of five grammes. His prescription for an adult is:

℞. Naphtha . puriss,
Sacchar. alb.....āā 5.00 grammes.
Olei bergamot.....0.03 gramme.
M. Sig.—Pulv., div. in chart No. xx. Sig.—5 to 20 daily.

The administration of naphthalin causes the fæces to be perfectly disinfected and odorless. Its action in cases of chronic diarrhœa is rapid, and most cases, if uncomplicated, are cured in from five to fifteen days. Dr. G. V. Liebig, of Reichenhall, subsequently reported a good result from enemata of naphthalin in a case of dysentery (*Bayr. ärztl., Intell.* Bl. xxxi. 29, 1884).

Dr. Ph. Pauli, of Lübeck (*Berlin, Klin. Woch.*, No. 10, 1884), used naphthalin with good success in the intestinal catarrhs of children. He observed, however, in two cases, some unpleasant after-symptoms, and he expresses the opinion that the drug should be given to small children with care, and that they should be watched. Not more than three ns every three hours should be given to children two years old.

Dr. E. Lehmann observed good results from naphthalin in two cases of chronic intestinal catarrh. In another case he noted some unpleasant effects, resembling strangury, from the drug. In acute diarrhœa, and in the vomiting of children, naphthalin has been given with contradictory results. In dilated stomach, and in the diarrhœa of phthisis, naphthalin has sometimes succeeded and oftener failed (Schutz, Cagnoli, Ewald, Pauli).

Several observers have found that naphthalin given in large doses will, at times, cause a slight bladder

catarrh, burning urine, and even strangury, but Rossbach contends that these accidents can be avoided by beginning with small doses and gradually increasing them.

It is in connection with typhoid fever that the claims for naphthalin are greatest. Rossbach and his assistant, Dr. Götze, believe that it has the power of shortening the course of this disease, lowering the temperature, and, if given early, of even aborting an attack. The *Therapeutic Gazette* gives the following account of Götze's observations, made upon twenty-five cases:

"All cases, with the exception of three, were uninterruptedly treated with naphthaline during the entire typhoid process, all other medication being excluded. The administered dose was one gramme (fifteen grains) and five to seven grammes *pro die*. (The drug used was, according to Rossbach's recommendation, always the purissimum resublimatum with the oil of bergamot.) In the course of the disease all patients had used over seventy grammes (two and one-third ounces), some even as much as one hundred and fifty grammes (four and one-half ounces).

"Untoward secondary effect was noted only in a single case, in which toxic symptoms, marked by cerebral functional depression, set in. The general course of all cases was exceptionally favorable, and the benign character of the intestinal symptoms very pronounced. In three cases an actual abortion of the affection appeared unquestionable; other cases coming under treatment early terminated in six to ten days, in others the fever did not last beyond sixteen days; while in another series the duration of the disease was not shortened at all, though the period of thermal elevation was sensibly shortened. Three cases perished from grave complication, though not from the typhoid process itself. Of considerable interest are the comparative trials with antipyrine and naphthalin. Repeated observations convinced Götze that naphthalin promptly reduced the febrile temperature in cases in which antipyrine (given in antifebrile doses) proved useless."

Democracy and Medicine.—In the name of freedom a Mr. Lowry recently introduced into the House of Representatives the following joint resolution: "Resolved, by the Senate and House of Representatives of the United States of America in Congress assembled, that it shall be a misdemeanor, punishable by a fine of five hundred dollars and dismissal from office, for any officer of the United States Government, civil, military, or naval, to make discrimination in favor of or against any school of medical practice, or its legal diplomas, or its duly and legally graduated members, in the examination and appointment of candidates for medical service in any of the departments of the Government. Section 2. That all such examinations shall be open to the attendance and witness of all physicians, citizens of the United States; and that duly certified copies of the complete records of all the details of said examinations shall be placed on file in the office of the Librarian of Congress, subject to the inspection and use of members of Congress."

When Doctors Disagree.—"The value of phosphorus in many diseases of nervous origin is too well known to call for comment."—*Dr. William Murrell.* "In my private note-book I attach to phosphorus the name 'humbug.'"—*Dr. Samuel Wilks.*

News of the Week.

A Boston Polyclinic.—The Boston physicians who have been giving "Clinical Courses of Instruction in Medicine" have organized a "Polyclinic" for the better prosecution of their work. We are glad to note this evidence of medical enterprise, but regret that our cultured confrères have adopted the unauthorized and artificial spelling of the word to which the misguided orthographists of New York gave birth. There is no such word as "Polyclinic" in any standard dictionary, general or medical. Our learned contemporary also speaks of the "Vienna Polyclinic," an institution which the Viennese would not recognize. "Policlinic" is a word sanctioned by years of usage, and applied to just such institutions as are now being organized in this country. There is no need of a new word.

Dr. John Dickson, one of the oldest and most prominent physicians of Pittsburg, Pa., died on January 8th, from the effects of injuries sustained by a fall some months ago.

The New York City Board of Health condemned and destroyed, in the last calendar year, 799,410 pounds of meat and fish, 212,000 pounds of fruit, 37,905 pounds of canned goods, 72,700 pounds of candy, and large quantities of other kinds of food whose consumption would have raised the death rate. Since January 1st the department has been forced to dismiss many of its inspectors, including several whose duty was the inspection of meat, fish, and milk, and to cut down the salaries of others who remain in the service.

A Surgical Feat.—Dr. Samuel W. Francis says that a clever chiropodist can change the "toe callous" into the Το Κάλον!

Pass and Pluck in Prussia.—In the nine Prussian Universities, during the session of 1884–85, 569 doctors and candidates in medicine were examined for the license to practise (*Venia Practicandi*). Of these 120 presented themselves for the second time, the remaining 449 being new candidates. More than seventy-five per cent. passed (430), 4 of these with the mark "very good," 270 with "good," and 156 with "satisfactory." Berlin had 221 candidates, of whom 64 failed or retired; Griefswald, 80, with 16 failures; Halle, 65, with 14 failures; Breslau, 64, with 15 failures; Göttingen, 37, with 8 failures; Kiel, 31, with 10 failures; Bonn, 30, with 2 failures; Königsberg, 28, with 8 failures; and Marburg, 13, with 2 failures.

A Severe Epidemic of Small-pox is reported to be raging in Vienna.

Laicization of Paris Hospitals.—It is stated that the resolutions recently passed by the Paris Municipal Council relative to the secularization of the hospitals of that city are being put into execution. The Sisters of Mercy in the Cochin Hospital have been ordered to vacate the premises, and their place will be taken by a new staff of lay attendants. It is the intention of the Council to banish, if possible, the religious element from every one of the hospitals, including the Hôtel Dieu.

THE CHOLERA is reported to have broken out in Venice.

"THALLINIZATION" IN THE TREATMENT OF TYPHOID FEVER.—Professor P. Ehrlich and Dr. B. Laquer, of Berlin, announce that by giving thallin almost continuously in grain doses every one or two hours, or half-grain doses every half hour, they are able to keep down the temperature of typhoid fever almost to normal, and materially to relieve the symptoms. From one to three grammes of the drug are given daily.

PRIZES GIVEN BY THE ACADÉMIE DE MÉDECINE.—On December 15th, the Paris Académie de Médecine bestowed fifteen prizes to the amount of nearly 24,000 francs, or about $5,000.

THE QUESTION OF PROFESSIONAL SECRETS.—An eminent French judge has just publicly delivered an important opinion on the subject of professional secrets. According to French law, Article 378 of the Code, all physicians, surgeons, midwives, or druggists who may become possessed of secrets by the practice of their profession are forbidden to reveal them, except in certain cases laid down by the law, where they are obliged to denounce criminals. Infraction of the law involves a punishment by a fine of about one hundred dollars and imprisonment of from one to six months.—Cor. *Philadelphia Medical Times*.

THE SUCCESSOR TO THE LATE PROFESSOR ROBIN is announced to be Dr. Mathias Duval.

THE WINES OF COCA have become both numerous and popular. Several analyses made by Dr. Charles L. Mitchell confirm the view that many physicians have reached, that most of the virtues of coca-wine are due to the alcohol. The amount of cocaine in the pint bottles ranges from one-fifth of a grain to four grains, or from six grains to thirty-three grains of leaves per ounce. Many of the coca-wines have less than two grains to the bottle. Assuming the dose of cocaine to be from one-fourth to one-half of a grain, it is not perhaps desirable that there should be more than two to four grains of the alkaloid in a pint of wine. Dr. Mitchell gives it as one-fifth of a grain of the alkaloid, or thirty to forty grains of the leaves, to an ounce of the wine.

OTHER TRAINING-SCHOOLS FOR NURSES IN INSANE ASYLUMS.—Referring to our editorial on the Training-school for Nurses at the Buffalo State Insane Asylum, Dr. J. C. Shaw, Superintendent of Kings County Insane Asylum, sends a circular giving an account of the establishment, February, 1885, of a training-school in his asylum. The school is in charge of Miss Hawley, assisted by Miss Fay. A course of study and work lasting two years is required. Dr. Shaw writes that a school is, he thinks, being organized in connection with the State Asylum at Norristown, Pa.

A THIRD ASYLUM FOR THE INSANE in Michigan, has recently been completed at Travers City, and patients have been transferred to it from the other over-crowded institutions.

SURGICAL SERVICES THROWN IN.—The following, from a practitioner of this city, will explain itself:

"I enclose part of a letter which I have recently received. The writer is a man of fair means, and has heretofore paid moderate fees. He has been to the Presbyterian Hospital, and evidently has money enough to provide himself with the luxury of a room 'this season of the year,' but he seems to regard the *surgeon* as a part of the bed-clothes, and included in his $15.00 per week.

"'At the Presbyterian Hospital all they charged was for room. Everything there included, such as *nurse*, *surgeon*, and medicine, etc. If I went in a *ward* it was *one dollar* a day and everything included, but I do not wish to go in a ward this season of the year.'"

A POSTHUMOUS TREATISE ON MEDICINE.—A literary event of interest in London medical circles is the publication of the long-expected work by the late Dr. Hilton Fagge, on the Principles and Practice of Medicine.

TELEPHONES FOR THE SICK CHAMBER.—A London firm has devised a telephone by which persons suffering from contagious disorders can safely communicate with their friends.

THE LATE DR. EPHRAIM J. CLARK, OF STATEN ISLAND, N. Y.—At a regular meeting of the Medical Society of Richmond, the following resolutions, commemorative of the death of Dr. Ephraim J. Clark, were unanimously passed:

"*Whereas*, in the providence of God, after a long and useful life, our revered friend and venerable fellow-member of the Medical Society of the County of Richmond, Dr. Ephraim J. Clark, has entered into his eternal rest, Therefore, be it

"*Resolved*, That in the death of Dr. Clark our Society has lost not only its oldest member, but the sole representative of the old school of physicians, so distinguished for urbanity, courtesy, and strict professional etiquette.

"*Resolved*, That his memory be cherished and his example emulated by us, his survivors, as a faithful and obliging friend, a kind and skilful physician, a willing and trusted counsellor, and a courteous Christian gentleman.

"*Resolved*, That the sympathies and condolence of this Society are due, and are hereby tendered, to the family and relatives of our deceased brother, in the belief that their loss is his eternal gain.

"*Resolved*, That these resolutions be engrossed in the archives of this Society, and that a copy of them be sent to the family of the deceased."

THE HOSPITAL SUNDAY COLLECTION amounted, at last accounts, to $35,361.07.

CARING FOR THE INSANE.—In illustration of our criticisms recently made upon this point, we would call attention to the fact that the New York City Female Lunatic Asylum, which has a capacity for 1,250 patients, contained, on October 1st, 1,628, or over 400 in excess.

THE POPE is reported to be suffering from morbus Brightii, and he has summoned, one Dr. Mezger, of Amsterdam, a specialist in that disease (!), to Rome, in order to receive advice and treatment from him.

THE LARGEST CALCULUS ever successfully removed from the bladder was by DR. DUNLAP, of Springfield, Ohio. It weighed over twenty ounces. So says the *Medical Age*.

MEDICAL SOCIETY, STATE OF NEW YORK.—Additional papers to be read at the next meeting of the Medical Society of the State of New York: "The Clinical *vs.* the Microscopical Evidences of Disease," H. C. Coe, M.D., New York; "Hints on the Treatment of Diphtheria," J. M. Bigelow, M.D., Albany; "The Curative Potency of Prolonged Sleep," J. Leonard Corning, M.D., New York; "Non-venereal Syphilis," L. Duncan Bulkley, M.D., New York; "Diet in Cancer," Ephraim Cutter, M.D., New York; "The Prognosis and Treatment of True Lateral Curvature of the Spine," Newton M. Shaffer, M.D., New York; "Bacteria, Identification and Classification of Species," William Hailes, Jr., M.D., Albany; "Hemorrhoids in Pregnancy," W. H. Bailey, M.D., Albany; "Relation of State Boards of Health to Local Boards," Maurice Perkins, M.D., Schenectady; "On the Adoption of some General System of Distributing the Insane of New York State, making Use of the Existing Asylums, and Providing for the Accommodation in each of both Acute and Chronic Insane," Frederick Peterson, M.D., Poughkeepsie.

NEW YORK PATHOLOGICAL SOCIETY.—Officers for the ensuing year: John A. Wyeth, President; T. Mitchell Prudden, Vice-President; Wesley M. Carpenter, Secretary; John H. Hinton, Treasurer; John C. Peters, Editor; Frank Ferguson, Assistant Editor; John C. Peters, T. Mitchell Prudden, L. Emmet Holt, W. P. Northrup, L. Waldstein, Committee on Admissions and Ethics; H. Marion Sims, E. C. Wendt, Members of Committee on Publication. The names of all in arrears in dues four years and more were dropped from the roll.

HOT AËRATED WATERS.—A method has been devised by Mr. Edward Warker, of this city, by which it is possible to raise carbonic acid water and other aërated beverages to any desired temperature, while keeping them at the same time fully charged with the gas. This is effected by passing the fluid through pipes surrounded by hot water, and the contrivance is so simple that it can be used without trouble at the bedside.

Reviews and Notices.

A GUIDE TO THE PRACTICAL EXAMINATION OF THE URINE. By JAMES TYSON, M.D. Fifth Edition, pp. 249. Philadelphia: P. Blakiston, Son & Co. 1886.

THE writer in this edition brings his work up to date with reference to the new and delicate tests for albumin, and with reference to the presence of proteids in the urine and the methods of detecting them. Otherwise the book is very nearly the same which has been found useful by so many in their pursuit of information on this subject.

A CHART OF PHYSICAL SIGNS OF DISEASES OF THE HEART AND RESPIRATORY ORGANS. Compiled from the Works of various Authors, with Original Ideas and Observations. By R. C. M. PAGE, M.D., Instructor in the New York Polyclinic, and Attending Physician for Diseases of the Heart and Lungs to the Northwestern Dispensary. New York: Press of Stettiner, Lambert & Co. 1885.

THE title of this chart explains itself. The tables are concise and well arranged, and are calculated to be of real value to the student or young practitioner who has not yet had the significance of the various thoracic sounds engraven in his memory by practical experience.

DISEASES OF THE NOSE AND THROAT. By CHARLES E. SAJOUS. Pp. 439. Philadelphia: F. A. Davis. 1885.

DR. SAJOUS has brought together his lectures, delivered at the Jefferson Medical College, on rhinology and laryngology. The hundred illustrations colored to represent the anatomical and pathological conditions of the parts under consideration make the work unique and exceedingly valuable. The perseverance and ingenuity of the author, who is also the artist, excite admiration. The text itself will interest and aid the practitioner in search of minute details for the better examination and treatment of diseases of the nose and throat.

ORGANIC MATERIA MEDICA AND THERAPEUTICS. By JAMES YOUNG SIMPSON, M.D. Pp. 337. New York: J. H. Vail & Co. 1885.

THIS manual of the organic preparations of the pharmacopœia presents, in a condensed form, the name, properties, and general effects of each drug. While intended primarily for students, it is yet a valuable acquisition to the library of anyone desiring to refresh his memory. It is arranged in accordance with the "Sixth Decennial Revision of the United States Pharmacopœia." Dosage is given in terms both of the old and the metric systems. A new feature is a list of common names for preparations, *e.g.*, Friar's Balsam, Compound Tincture of Benzoin, etc. This will prove of great service to the student. The typographical appearance of the book is excellent, and it deserves a wide sale.

AN INTRODUCTION TO THE STUDY OF THE DISEASES OF THE NERVOUS SYSTEM, being Lectures delivered in the University of Edinburgh during the Tercentenary Year. By THOMAS GRAINGER STEWART, M.D. 8vo, pp. 237. Philadelphia: J. B. Lippincott Company. 1885.

THE first three chapters cover the subjects of the medical anatomy of the nervous system. The author gives a very good account of this subject, well illustrated by cuts which are mostly old, but to which are added some heliotype representations of sections of the brain. Certain of our expert cerebral anatomists might learn something from the nicety with which these latter are done. The lectures from the fourth to the twelfth are taken up with a description of the method of examining the nervous system. This part of the work is an extremely interesting and instructive one, and should be thoroughly studied. The closing chapters are devoted to some considerations regarding the pathology and treatment of nervous disease. Many physicians who feel a desire to acquaint themselves with modern neurology, but who feel somewhat afraid of the supposed heavy task, will find Dr. Stewart's book just the thing desired. It is clear, systematic, and accurate. It does not pretend to be complete and exhaustive.

PRACTICAL SUGGESTIONS RESPECTING THE VARIETIES OF ELECTRIC CURRENTS, AND THE USES OF ELECTRICITY IN MEDICINE, with Hints relating to the Selection and Care of Electrical Apparatus. By AMBROSE L. RANNEY, M.D. Pp. 147. New York: D. Appleton & Co. 1885.

THIS is a useful little work, presenting in a brief way the subject of electro-technique and electro-therapeutics.

THE EXTRA PHARMACOPŒIA, with the Additions introduced into the British Pharmacopœia, 1885. By WILLIAM MARTINDALE, F.C.S. Medical References, and a Therapeutic Index of Diseases and Symptoms. By W. WYNN WESTCOTT, M.B., Lond. Fourth edition. 16mo, pp. 416. London: H. K. Lewis. 1885.

THIS little work gives an account of many drugs and chemicals in practical use, but not officinal. It is useful for reference, now that so many new drugs are being forced upon one's notice.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 7, 1886.

ABRAHAM JACOBI, M.D., PRESIDENT, IN THE CHAIR.

DR. R. H. DERBY, from the Special Committee consisting of Drs. Agnew, C. S. Bull, Webster, G. M. Smith, Derby, and the President *ex officio*, made a report on

COMMUNICABLE EYE DISEASES

in asylums and residential schools in this city and vicinity.

This Committee has been aided in its work by Dr. J. J. Milhau, representing the State Board of Charities, Mr. Arthur G. Sedgwick, of the State Charities Aid Association, Mr. Elbridge T. Gerry, of the Society for the Prevention of Cruelty to Children, and Mr. James Gallatin, representing the New York Association for Improving the Condition of the Poor.

The Committee has secured an examination of the eyes of the children in *fifty* asylums and residential schools. These examinations were conducted by experts in ophthalmology, who accompanied sanitary inspectors sent by the Board of Health, and the experts included men of the standing of Roosa, Loring, Noyes, Mittendorf, giving ample guarantee that the inspection would be conducted in the most thorough manner.

As samples of the reports made by the inspectors, those from the Deborah Orphan Asylum, 95 to 103 East Broadway, the Roman Catholic Orphan Asylum, Fifth Avenue and Fifty-first Street, and the St. Joseph Asylum, Eighty-ninth Street and Avenue A, were read, giving a total of 1,134 children, of whom 590 were found suffering from communicable eye disease.

The general conclusion of the report was that a worse condition of things exists now than was found when the inspections were made which formed the basis of the preliminary report made by the Committee in June last. The reports submitted showed that the physicians who have charge of these asylums make no systematic inspection of either the buildings or their inmates; that no adequate system of quarantine is practised; that many of the asylums are grossly overcrowded; and that in nearly all the children are admitted without due examination of their physical condition, especially with reference to their eyes.

The report concluded with a copy of an Act for the better preservation of the health of children in institutions, written by Mr. Gerry, endorsed by the Committee, and to which the Academy gave its approval. The proposed Act provides for careful examination of the eyes of each child applying for admission to an institution, forbids the entrance or remaining in contact with children not affected with contagious or infectious eye disease, and prevents overcrowding.

THE TREASURER'S REPORT,

DR. W. F. CUSHMAN, Treasurer, showed a balance in favor of the Academy of $880.58. During the last year fifty-five new Fellows have been admitted.

DR. F. A. CASTLE, Treasurer of the

BOARD OF TRUSTEES,

reported a balance of $647.12; that the library fund is $4,548.66; that the general permanent fund is $1,280.74; and that there is a balance of $137.80 of the fund for the liquidation of the mortgage.

THE COMMITTEE ON LIBRARY

reported that the library contains 27,000 bound volumes, 9,500 pamphlets; that during the last year there had been donated 1,320 bound volumes, 1,214 pamphlets, and 23,865 journals; and that there had been 4,360 visitors.

Other annual reports were read by title and referred, and the Academy then passed to the consideration of proposed

AMENDMENTS TO THE CONSTITUTION AND BY-LAWS.

The more important of those adopted are the following: The Committee on Medical Education and the Committee on Medical Ethics were abolished.

The Academy retained its power to discipline its Fellows by adopting the following section, introduced by Dr. Agnew:

"The Council shall, on a written statement signed by a complainant and duly forwarded to the Secretary, take cognizance of any complaint against a Fellow. The Council may, after investigation, dismiss the complaint or transmit its findings for further action by the Academy."

Other clauses in the By-Laws provide that:

"The Academy may suspend or expel a Fellow."

"The public shall be invited to listen to the Anniversary discourse."

"Each Resident Fellow on admission shall pay an initiation fee of *twenty-five* dollars; the dues shall be remitted during the year in which fellowship is acquired."

"Any Resident Fellow who is qualified to vote at an annual election, and has paid five annual dues, may compound for all future annual dues by the payment at one time of one hundred dollars."

OFFICERS FOR THE ENSUING YEAR.

The Tellers reported that the following had been elected:

Vice President—Henry D. Noyes.

Corresponding Secretary—Wesley M. Carpenter.

Treasurer—William L. Chenault.

Trustee—George A. Peters.

Member of Committee on Library—I. H. Emerson.

Member of Committee on Ethics—S. Oakley Vander Poel, Sr. (Committee abolished by Amendments to Constitution and By-laws).

Member of Committee on Education—D. B. St. John Roosa (Committee abolished as was the Committee on Ethics).

Recording Secretary—Arthur M. Jacobus.

Members of Committee on Library—W. H. Katzenbach (full term), Laurence Johnson (short term).

Delegates to the Medical Society of the State of New York (elected by the Academy, formerly appointed by the Council)—W. R. Birdsall, R. W. Amidon, A. S. Hunter, W. E. Bullard, and G. Bacon.

The Academy then adjourned.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, December 4, 1885.

BEVERLEY ROBINSON, M.D., PRESIDENT, IN THE CHAIR.

DOUBLE HARELIP.

DR. R. F. WEIR presented two infants upon whom he had operated for double harelip. In one the complication of an attachment of the inter-maxillary bone to the tip of the nose existed. By the operation adopted in this case, a V-shaped piece of the vomer was removed, the inter-maxillary process crowded backward and fitted into the space between the alveolar borders of the maxillary bone on either side, and the nipple-like process of skin utilized in forming the tip. In both patients the result was unusually good.

DR. C. L. DANA read the paper of the evening (see page 57), entitled

THE RELATION OF LITHÆMIA, CALCULI, AND PHOSPHATURIA TO NERVOUS SYMPTOMS.

DR. W. H. DRAPER said he had listened with great interest to Dr. Dana's paper, and was quite prepared to agree with what he had said regarding the impropriety of creating a diathesis based on the presence of ox-

alate of lime, uric acid and its salts, or the phosphates in the urine. He had long been interested in the association of functional nervous disturbances and these conditions, but with regard to their association with a rheumatic rather than with a gouty taint, he was not quite so clear as to the distinction to be drawn between gout and rheumatism as to be able to say that the lithæmic state did not indicate a gouty habit as positively as it did a rheumatic one. He believed that gout and rheumatism were so nearly alike that it was hardly possible to dissociate them. The fact that uric acid had long been regarded as the materies morbi of gout had fixed in the minds of people the idea that it was the essential cause of this malady, but he believed there were a good many who doubted whether uric acid was anything more than a result of certain changes in the condition of the blood going to excite gout, and that the uric acid itself was not necessarily a cause of that disease. In other words, that there could be gout without an excess of uric acid in the blood. He had often thought that, by careful inquiry into the family histories of persons suffering from nervous disturbances associated with lithæmia, it would be found that there was a gouty tendency. Such, at any rate, had been the result of his own observation. The person suffering from the functional nervous disturbance might himself be free from arthritic disease. It is common enough to find in the same family cases of glycosuria, gout, and lithæmia; therefore, Dr. Draper could not see why we should not speak of lithæmic disease as gouty disease, just as we would speak of gouty disease as lithæmic disease; or, of lithæmic symptoms as gouty symptoms, just as we would speak of gouty symptoms as lithæmic symptoms. Another point which he thought allied them was the fact that they were relieved by the same hygienic and dietetic recommendations. In his experience the gyclosuric were not more relieved by nitrogenous diet than the lithæmic subjects. This might seem like a broad and strong statement, but it was based upon a very large personal experience, and he thought it was confirmed by the experience of others.

Dr. Dana had not treated of the management of these conditions, and he wished, therefore, to say a few words with regard to the dietetic management, especially of the lithæmic state. He could probably best do this by the relation of a case which came under observation two or three years ago, in which the patient presented in a striking manner most of the functional nervous derangements associated with this state. The patient was a married woman who had been travelling in Europe a number of years. She had gouty antecedents, but had never had gout herself. She began to suffer, shortly before her return to this country, from a great variety of nervous disturbances—parasthæsia of all sorts, with great nervous depression; she was melancholic, apprehensive, feared to go out alone, was subject to attacks of dizziness and of numbness of the extremities. She consulted a physician in London who told her she was threatened with apoplexy, and she came home in great terror. When Dr. Draper saw her she was in a pitiable condition, afraid to stay in her room alone, afraid to go out, had alarming attacks of vertigo, would awake in the night with numbness and coldness of the extremities, associated with pallor. The arms and legs at times had the appearance of marble, being perfectly numb and cold. This state would return frequently, two or three times during the night. The urine was found to contain an enormous amount of free uric acid; it was very acid in reaction, and of high specific gravity, and always deposited urates and oxalates. She had the usual dyspeptic symptoms which are associated with such nervous disturbances, a great deal of acid eructations, occasional attacks of diarrhœa alternated with constipation. What was of rare occurrence in his experience, the patient was unable to use alkaline medication; she could not take soda or potash in any form in which he could present it to her. She had been in the habit of taking a mixed diet and wine. Dr. Draper withdrew everything in the form of carbo-hydrates, allowing her only animal food and milk. The urine rapidly changed in character, becoming clear, of lower specific gravity, and free from crystalline deposits, or the deposits of the salts of uric acid. With this change in the urine there came a coincident change in the nervous symptoms. She ceased to have vertigo and the distressing attacks of numbness. The patient had been more or less under his observation since that time, and she informed him that she was unable to use any bread, or any starchy or saccharine food whatever. If she ate bread there would be an immediate return to the uric acid sediments, dizziness, palpitation, and numbness which before distressed her. She had become quite thin; she had before been quite stout; but so long as she continued the nitrogenous diet and milk she enjoyed a very fair degree of health. This was an extreme illustration of what he was sure the experience of all who had tested the value of a nitrogenous diet, or the withdrawal of carbo-hydrates and saccharine foods from the diet of persons suffering from lithæmia, would confirm. He regarded the dietetic management as being by far the most important element in the treatment of these cases. Medication was a secondary matter. Alkaline remedies were, of course, useful, and often necessary.

In addition to the nervous disturbances which characterized the lithæmic state, Dr. Draper thought this condition was often responsible for chronic catarrhal affections, most often of the gastro-intestinal tract, but not infrequently of the respiratory tract. Whether these lesions were brought about by the same changes which provoked the central nervous disturbance or not, he was unable to say. It would seem as if the nervous disturbances were the result of certain vaso-motor derangements, provoked by the condition of the blood, which characterized these cases, and it seemed not improbable that the trophic derangements had a similar origin. In these cases also he believed the dietetic management of most importance.

Dr. E. D. Hudson, Jr., said his views regarding so-called lithæmic and neurasthenic cases had changed somewhat from time to time. At one time he regarded the cases as largely of a neurotic nature primarily, but his views had gradually changed, until he had come to the conclusion that the majority of neurasthenic cases—cases in which there was prostration and functional nervous disorder—were of lithæmic origin, and that the liver was the organ especially at fault. He appreciated the importance of reaching more definite conclusions regarding the nature of these cases by making such observations as Dr. Dana had made—examinations of the urine, etc. At one time he felt pretty sure that uric acid or oxalate of lime existed pretty uniformly in this class of cases, but he had since had opportunity to watch two or three cases for a long period of time, and he had found such great variations in the character of the urine, in the quantity of urinary salts, etc., that he had come to feel that the quantity of urine passed or the kind of salts it contained were of little value. It seemed to him pretty evident that most of these cases occurred in persons of rheumatic or gouty diathesis. He had seen one case in which there was a singular transition from acute and subacute rheumatism to lithæmic symptoms. The patient would have rheumatic tendencies for a period, which would disappear, when he would begin to suffer from lithæmic symptoms, pertaining to the nervous system, etc.; and after being treated for this, there would be a return of the rheumatic symptoms.

The treatment which he had tried had been based upon the different theories as to the cause of the condition. He had not found the treatment, based upon the view that the condition was chiefly a nervous disorder, to be successful. Such remedies as are considered tonic in these conditions—quinine, alcohol, wine, fluid extract of coca, etc.—might relieve these neurasthenic patients of their depressed state for a brief period, but it was a form

of exhilaration which soon gave way to a depression even greater than that which had previously existed. He had, therefore, come to discourage the use of such remedies. Within a few months he had directed treatment more especially to the regulation of the hepatic function, by administering podophyllin, extract of colocynth, dilute muriatic acid, in a bitter tonic, and in a large proportion of cases the results were very good. In addition, he generally restricted the patients to a nitrogenous diet—meats, stale bread and butter—avoiding saccharine and starchy foods, and especially fruits. Still, in the treatment of all cases of this class Dr. Hudson had found that the patients tired of one diet, and he had recently tried the method of allowing the patient to eat of almost everything, and he was somewhat surprised that they had remained free from lithæmic symptoms; and the opinion had been gaining ground with him that, after all, gastric indigestion and direct influence upon the pneumogastric nerve might have something to do in the causation of the condition. There seemed to be an immediate disturbance, in many cases in which digestion was deficient, before it would seem that an acid or poison could form within the system to cause such a variety of nervous symptoms. He always bore in mind a remark by Dr. Flint, that in dyspepsia, as a rule, methods of exclusive diet were not desirable. Probably the same remark would apply to the cases under consideration, and, besides, there should be regular exercise and means taken to stimulate the superficial circulation and to regulate the hepatic function and the stools. By the use of such remedies as nitro-muriatic acid, or bitter tonics, Vichy water, lacto-peptine with bismuth or soda, and something to stimulate the pneumogastric nerve, such as cubebs or ginger, he had found patients who had been treated unsuccessfully by other methods for indigestion and associated nervous symptoms, soon able to eat a promiscuous meal three times a day. Perhaps, however, he would yet meet with cases in which this method of treatment would be unsuccessful, but the facts which he had accumulated went far to prove that the improvement was not simply imaginary, inspired by hope in a new method of treatment.

Dr. G. B. Fowler had examined a great many specimens of urine, and had for a long time kept accurate records of such examinations, and he must say that he believed there was such a thing as oxaluria. The majority of cases of so-called nervous dyspepsia presented constant and marked depositions of oxalate of lime. But in order to determine this it was not sufficient to examine one specimen of urine to-day and another three or four weeks hence. The patient should bring his urine for examination every day for at least a week, for the sources of oxalate of lime in the urine were many, and they might be trivial or otherwise. It might be due directly to the food taken, for certain kinds of food contained an excess of oxalate of lime, and it might appear in the urine without indicating anything pathological. Again, its presence might be due to the food indirectly, because of faulty digestion. It might also be due to insufficient oxidation, for oxalic acid is one of the end products of complete assimilation, and if, through respiratory or cardiac disease, or blood-disease which impairs oxidation, the elements which are thrown off as a result of combustion in the tissues are not sufficiently oxidized, the higher retrograde products, uric acid, oxalic acid, would appear; but in the majority of instances oxalic acid is due to catarrh of the intestinal tract. The presence of acid fermentation gives rise to flatulence, pain, reflex irritations, etc. He therefore thought there is such a thing as oxaluria, not a primary affection, but secondary to interference with digestion. The same might be said of uric acid and phosphates in the urine.

As to treatment, he was decidedly in sympathy with Dr. Draper regarding the value of a nitrogenous diet. He had seen a great many cases of most marked nervous disturbance, some having about all the symptoms of locomotor ataxia, ultimately relieved by persistent use of nitrogenous diet. He was himself an example. Three years ago he did not weigh more than one hundred and ten pounds; he suffered from marked nervous symptoms, such as involuntary tremors which caused his bed to shake, from flatulence, and other gastro-intestinal disturbances. These symptoms passed away when he confined himself to a nitrogenous diet, and he now weighed one hundred and fifty pounds. When Dr. Salsbury made public his views regarding the appearance of the blood in hog-cholera, dyspepsia, etc., through the columns of The Medical Record in 1861–62, they were not accepted with great favor by the profession; but the success of his mode of treatment could not be disputed, and it was due to the use of a nitrogenous diet. So far as his examinations of the blood were concerned, Dr. Fowler was not able yet to express a definite opinion, but he had examined about five or six hundred specimens of blood of which he had kept records. He had observed one thing, that in marked cases of flatulent dyspepsia there was a large number of colorless blood-corpuscles which were not seen in a state of health. In the healthy person the fibrinous mesh was coarse, while the fibres themselves were fine, but in dyspepsia it was found that the meshes were fine while the fibres were coarse, and there were many of these colorless corpuscles entangled in them. Now, if the fibrin depended upon the liver, and the liver was at fault in dyspepsia, it held to reason that in dyspeptic cases we should find more fibrin in the blood. He gave scraped meat, or the pulp, cooked enough to make it palatable, peptonized milk, and plenty of water, which was the great solvent or means by which to cleanse the system.

Dr. A. A. Smith thought that if a physician of fifty years ago could have been present, he would have thought the discussion on this subject simply amounted to a refined explanation for treating the liver in the manner that he had been accustomed to. It seemed to Dr. Smith that we move in cycles. Dr. Hudson had suggested the same idea. Dr. Smith had been taught fifteen years ago that it was not necessary to pay so much attention to the liver; that it was hardly to be regarded as the cause of original sin, and that it was not necessary to direct treatment to this organ in a routine way, as it had been done for many years, giving every patient a dose of calomel or other cathartic which would act upon the liver. But when he became actively engaged in practice, he found that his teachers had paid too little respect to the liver. His own respect for it was constantly increasing. For instance, even in malarial poisoning he would give a cholagogue—not before giving quinine, but in connection with quinine; and he felt quite sure that such treatment would be of great advantage in digestive complaints, such as had been spoken of this evening. Further, he believed that in many cases of organic disease, whether of the respiratory or circulatory tract, and even in some organic diseases affecting the alimentary canal, we could delay the progress of the disease, or certainly make the patient more comfortable, by resorting to the same kind of treatment. In other words, he wished to put himself entirely in accord with much that had been said regarding the liver. There were cases of anæmia with much derangement of the alimentary canal, but not what is called pernicious anæmia, which were not only not benefited, but which were aggravated by the ordinary treatment with iron, etc. But by persistent, not depressing, treatment directed to the alimentary canal, the use of alkalies, cholagogue cathartics to a moderate degree, and the regulation of the diet, and after two or three weeks, perhaps, the use of ordinary remedies employed in such cases, the patients would recover much more quickly. The same remarks he thought would apply to the disturbances of the nervous system mentioned.

Dr. Dana was inclined to think most too much respect had been paid to the liver during the discussion.

He did not think we cured many of the cases under consideration by simply treating the liver. On the other hand, he thought we could get better results by administering strychnine, almost to the degree of poisoning, or by giving strong tonics, or by using such means as would arouse the tone of the general nervous system. He thought there was a pretty large class of cases in which the liver was not at fault at all. There was a class of cases described by Dickinson as having alkaline urine often, or urine containing earthy salts, which he said were injured as a rule by salines; here Dr. Dana thought the liver had nothing to do with causing the condition.

THE PRESIDENT had seen a number of cases with an inflammatory condition of the respiratory tract, such as referred to by Dr. Draper, there being the indications of the lithæmic state described by the speakers—namely, nervous symptoms, engorgement and torpidity of the liver, etc.; yet he had failed to give them much benefit from the general treatment advised by Dr. Draper, but had found local applications necessary.

GARDEN SLUG EJECTED FROM THE STOMACH.

DR. E. D. HUDSON, JR., presented a limax or ordinary garden slug, and said that, about a year ago, Dr. Stephen W. Roof brought him a fish-like animal or body, with the statement that it had been vomited by a young lady who was a sufferer from dyspepsia. Dr. Hudson was of the impression that it was a distoma crassum, but on showing it to Dr. Johnson, the naturalist, he was assured that it was an ordinary garden slug; and inasmuch as air-breathing animals were supposed not to be able to live in the stomach, they concluded the patient's story was not genuine. But about two months later, one of Dr. Hudson's patients, a lady aged twenty-two, unknown to the other patient, brought him a similar object, which Dr. Johnson also demonstrated to be a garden slug. There could have been no collusion between the two ladies, for they were unknown to each other. The animals were said to be alive when ejected. In the second case there was no garden belonging to the house. His patient was believed to be truthful.

The Society then adjourned.

Correspondence.

OUR LONDON LETTER.

From our Special Correspondent.

MEDICAL MEN IN PARLIAMENT—MEDICAL MEN AS ORATORS—PERIPHERAL NEURITIS—THE METROPOLITAN SEWAGE QUESTION.

LONDON, December 26, 1885.

THE estimate which I gave in a former letter as to the probable number of medical men in the new House of Commons has, I find, been slightly exceeded now that the election returns are complete. The new Parliament of 670 members contains 16 medical men. Some of these, however, left the profession years ago, others did so on entering the House, and the new medical members will probably soon follow their example. Parliamentary work is incompatible with professional work, and about the only instances I can call to mind of medical men continuing practice, are those of Dr. Lyons, the late Sir D. Corrigan, and the late Dr. O'Leary, all of Dublin.

By dint of rushing to and fro between London and Dublin they managed to retain some consulting practice, but scarcely sufficient, I should suppose, to adequately remunerate them for the expense of keeping up two establishments and the extra work and anxiety they went through. One of the present members, Dr. Farquharson, although retired from practice, has not withdrawn from the fields of medical literature since his entry on political life. As a rule, though, politics extinguishes professional interests. Those medical men who have sat in the House of Commons and made any name for themselves, have done so as politicians and not as medical men or even as sanitary reformers. On sanitary subjects, indeed, the voice of the profession has not been uplifted in the legislature as it ought to have been. But oratory is not a very common gift in our profession, although it certainly numbers several who may fairly claim to possess it. In this line Sir James Paget is *facile princeps* and the other medical baronets compare very unfavorably with him. Dr. Balthazar Foster, the new medical member for Chester, and President of the Council of the British Medical Association, is an excellent speaker. Mr. Brudenell Carter, the well-known ophthalmic surgeon, is as ready with the tongue (and I may add pen) as with his fingers in ophthalmic surgery. Mr. Rivington, of London, and Mr. Sampson Gamgee, of Birmingham, are both eloquent speakers, though they have been heard but seldom of late years. Both, however, were once more to the front last week at the meeting at the College of Surgeons.

In his recent "Harveian Lectures," Dr. Buzzard has recently directed attention to the important subject of paralyses caused by peripheral neuritis. Dr. Buzzard has shown that such cases are frequently by no means so simple as might be supposed. The symptoms are not always uniform and the neuritis may be multiple, thus rendering the problem somewhat complex. It is very important to diagnose such cases from similar paralyses due to central disease, and the prognosis of the former is much more favorable. Syphilis, gout, lead poisoning, alcoholism, diphtheria, and possibly some other of the acute infectious diseases, are enumerated as common causes of multiple peripheral neuritis.

Considerable attention has lately been devoted to the sewage question as affecting the inhabitants of London. The pessimists have had so much the upper hand of late, that I fear such of your readers as see any of our journals have formed somewhat exaggerated notions of the magnitude of the evil from which we suffer. In spite of all that they say, we, who are dwellers in London, have much for which to be thankful in sanitary matters. The system of main drainage is good and the main sewers are fairly well ventilated. Cesspools have been abolished.

Where "bad drains" are complained of, in ninety-nine cases out of every hundred it is the householder's own pipes which are at fault. The low death rate in London, compared with that of other cities, also points to the general excellence of our system of drainage. This result is, however, unfortunately only obtained at the sacrifice of our river. The Thames is still virtually a vast sewer, but the sewage is not poured into it in its course through London from innumerable drains as was the case twenty years ago, but is carried fourteen miles down the river. The present system of main drainage was commenced twenty years ago and completed ten years ago at a cost of nearly five million pounds sterling. Below the sewage outfalls, the river is very offensive and the dwellers on its banks in that part of its course are said to suffer, though no very definite evidence has yet been adduced on this point. The effect of the tide, also, is felt as high as London Bridge, so *some reflux* of sewage probably occurs. Nevertheless, the condition of the river compares favorably with its state twenty years ago. The chief difficulty in inaugurating any change is the vast bulk of sewage which has to be dealt with. Disinfectants have been lavishly used at the outfalls for several years now, but without any benefit at all proportionate to the sums spent. The latest proposal is to precipitate the solid matter, take it out to sea in barges, and there throw it overboard. Experiments with this method are shortly to be tried on an extensive scale.

THE CONTROLLING FACTOR IN THE DETERMINING CAUSE OF SEX.

To the Editor of The Medical Record.

SIR: Upon reading your editorial review of Mr. Terry's recent work upon "Controlling Sex in Generation," some thoughts occurred to me upon which I would like to receive information. I take it for granted that every physician has patients to whom, if he could impart the secret of "controlling sex," he could remove one stumbling block to domestic felicity—not to dwell upon the fact that there would thereby be born a greater number of that nowadays rare class, "welcome children."

From your article I judge that the work in question claims that the sex is governed by the relative degree of sexual excitement of the parents at the time of congress.

This idea has often been advanced, but, to my mind, not proved, though Mr. Terry seems to have reversed the effect of this greatest sexual excitement, by making the male generate a female instead of his own sex.

There is a degree of probability in the theory that energy will result in a greater effect than listlessness; but how can it be proved that this energy is transmitted to the spermatozoa or ovule, when to all appearances it is expended in the act of liberation of these two elements, spermatozoa and ovule.

Here allow me to suggest that none are so capable of testifying upon this subject as the one hundred and twenty thousand (?) physicians it is claimed that we have in the United States.

Of course, many will object, saying that they do not feel like giving information upon such a "delicate subject." I answer perhaps not. But under the law of compensation, they who all their professional lives are continually seeking "rather delicate" information cannot consistently refuse to contribute to the common stock.

To lead off, I do not think the theory advanced by Mr. Terry will hold, that is, if I may judge by the experience of some of my patients, and it certainly will not in my own family (we have had three children, all males).

Every adult person has speculated upon this question. I have come to the conclusion that it is a mystery; still, that does not stop me from speculating.

After examining all the works to which we have access, including all the human embryos within our reach, we cannot help but be surprised at the advanced stage the embryo attains before we can positively decide upon its sex.

My observations and readings have forced me to the conclusion that the sex depends upon the degree of development, differentiation, or evolution—whichever term suits the case the best—that the animal arrives at; in other words, that sex is merely a degree or phase of development.

To the lower orders we must undoubtedly go for our information. There we find that propagation first begins by division, whether the method by which it is accomplished is by fission, multiplication of the nucleoli, or by budding. Here the sex, if we recognize sex at all, must be termed female. As we ascend higher in the scale we find a sexual differentiation, and that the individual combines the two sexes in the one body. Next we find a separation of the sexes, the male having only a temporary existence, apparently only for the sexual act, and then dies, the female having a more permanent existence.

We can now find the male having a more permanent existence; first arriving at maturity as a separate individual, then permanently uniting with the female during her life, apparently forming a double-headed being, and giving rise to the original belief that it was a double-headed being. I refer to the worm that is the cause of the disease known as the "gapes" in chickens and other feathered creatures.

If we go to the bee for information, we find that the same egg, according to its environment, will develop into a neuter gender, the worker; or a fully developed female, the queen bee; or into a more highly developed being, a male, the drone.

Examine the ovaries of the frog; here we find the ovary develops into a testes, which we know to be the case of the higher animals; but in some females of this animal we can find ovaries which have passed on to the next higher phase of development, and in the same organ can be found ovarian as well as testical tissue; this seems to prove that the testes are a more highly developed, not simply differentiated, tissue.

It may be that the degree of maturity of the spermatozoa determines the sex, the most highly elaborated forming the male, and the less, the female. The degeneracy of the physical powers of an individual should affect the procreative function, and I have for some time regarded the excess of females in a family as indicating the physical degeneracy of that family. It appears to be the case that the more completely domesticated a race of animals become, the greater the ratio of females; their vitality seems to be lessened. The cat tribe is an instance; but I think that the peerage of Great Britain illustrates this perfectly, where the laws of entail and male succession to titles extinguishes the title by reason of lack of males in the family; while I know of no case where there was a lapse of title from lack of female descendants; and though such might be found as an exception only, that of the lack of male heirs is of frequent occurrence.

To return and examine the theory advanced by Mr. Terry. Every physician meets with cases of extremely unexpected and very unfelicitous pregnancies, some occurring during the mid-menstrual period, etc. These all go to confirm the researches of physiology, which teaches us that days can elapse between the date of departure of a spermatozoa and its arrival into port. It is a fact that a long time can pass before the wandering spermatozoa meets with its shipmate, who apparently has been weather-bound in the ovarian and peritoneal seas or the Fallopian gulf. At all events, enough time has intervened for the ardor of both their progenitors to have subsided, therefore leaving them without the impulse of the party having the "greatest sexual excitement;" from which I infer that excitement cannot be the determining cause of sex. Again, how about the sex of a fœtus whose mother conceived while under the paralyzing effects of fear? or while under chloroform, morphine, whiskey, or any partial or complete anæsthetic? Under Mr. Terry's theory the children should be all females, while under the ordinary ideas the children should be all males. But, I ask, are they? and if so, which?

To sum up, the present summit of sexual development seems to be the male, and I believe that the determining cause of sex is the degree of evolution that the being has arrived at. We do find individuals who are farther developed than a female, yet are not complete males. A complete male with ovarian tissue I do not recollect reading of, but I have, of females with a testicle.

At any rate, it is facts we are after, and for the good of our patients, let each physician contribute.

CHARLES AMBROOK, M.D.

A PLEA FOR PERSECUTED LISTERISM.

To the Editor of The Medical Record.

SIR: Professor Tyndall recently wrote: "A great theory has never been accepted without opposition. The theory of gravitation, the theory of undulation, the theory of evolution, the dynamical theory of heat, all had to push their way through conflict to victory. And so it has been with the germ theory of communicable diseases.

Some outlying members of the medical profession dispute it still. . . . Such must always be the course of things as long as men are endowed with different degrees of insight; where the mind of genius discerns the distant truth which it pursues, the mind not so gifted often discerns nothing but the extravagance which it avoids."

The latest attack upon the principles of the germ theory comes from the pen of the distinguished surgeon, Dr. Frank H. Hamilton, in THE RECORD of January 2d, in an article on "The Art of Primary Union, or Union by Adhesion, in Large Incised Wounds." Professor Hamilton enumerates four essential conditions for securing the above result, which may briefly be stated as: 1, Good general health; 2, removal of all foreign bodies; 3, presence of plastic lymph; 4, cleanliness and care in handling wound. In referring later to Lister and his disciples he states: "They omit nothing which in the opening of this paper I declared essential to success."

The advocates of antiseptic methods and their opponents are therefore agreed as to fundamental principles; they only differ in their views of the *modus operandi* of these principles, and it is under condition No. 2 that the difference is most manifest.

The advocates of antiseptic treatment believe that the atmosphere and all dust contain germs, which act as foreign bodies in the wound, and which should be removed and others prevented from gaining access to its interior.

Upon what basis does this belief rest? Pasteur has proved beyond question that fermentation and putrefaction are due to the presence of microscopic plants, and his observations have been confirmed by Tyndall, Burdon-Sanderson, Cohn, and a host of other scientists. In fact, if fermentable and putrescible liquids are deprived of these germs, putrefaction and fermentation do not occur, and the liquids remain unaffected indefinitely. Certain chemicals destroy these germs. Is it not rational to believe that if these germs are allowed free entrance to wounds they establish fermentative and putrefactive changes in the secretions, which produce irritation, and which must result in the formation of pus, and the defeat of condition No. 2? Is it not rational, therefore, to render the wound first *aseptic*, and later *antiseptic*, by the use of chemicals known to produce these results?

Dr. Hamilton also states: "Blood is a foreign body." The advocates of antiseptic methods will hardly accept this statement without some qualification. Is blood in a wound always a foreign body, and, therefore, a source of irritation? Cheyne tells us in his work on "Antiseptic Treatment of Wounds": "There is another mode of healing only seen in the case of wounds where aseptic treatment is thoroughly carried out, or in some rare instances where a crust forms; I mean *healing by organization of blood-clot*." And he quotes the investigations of Dr. H. Tillmaus, of Leipsic, to substantiate his views. He shows that a blood-clot in a wound may be subjected to mechanical or chemical irritation. Chemical, from external sources, or *by fermentation of the clot*. But fermentation only occurs through the agency of microscopic organisms, therefore it becomes a source of irritation only after allowing the entrance of germs in contact with the clot, which initiate fermentative changes, and it thereby becomes a foreign body. But exclude the germs, and the clot undergoes organization or absorption, and no longer constitutes a foreign body. This is beautifully illustrated in the case of simple and compound fractures. In the first, though blood may be extravasated, it does not act as a foreign body. But let an external wound communicate with the seat of fracture, and every surgeon knows how much more serious the case becomes. Why is the clot of blood so harmless in one case and such a source of irritation in the other? The atmospheric germs are responsible for the difference. In the one case it is organized or absorbed, in the other fermentative changes are induced, which render it a source of irritation, if not of inflammation.

Thus we see that these germs may act locally, causing irritation, and thereby promoting union by first intention. That these same germs may gain entrance into the blood and tissues and induce *systemic* changes, there is little room for doubt. With animals this has been demonstrated. Koch has shown that pyæmia is due to a micrococcus, which, isolated by cultures and introduced into the circulation of a healthy animal, reproduced the original disease. The same has been demonstrated with septicæmia in mice. The result will, no doubt, be analogous with *man*, but opportunities of demonstration by inoculation have so far been too few for solving the problem. Dr. Hamilton asks: "What treatment, either ancient or modern, has furnished a better record than this furnished by Alanson, Syme, Liston, Percy, and Lucas . . . these results were obtained before the introduction of anæsthetics or antiseptics." We are told these surgeons exercised the most rigid cleanliness and gentleness, the section of the soft parts was neat and regular, hemorrhage was carefully controlled, the flaps were accurately coaptated, without drawing or pressing, free drainage was instituted, and perfect rest secured.

Is it not possible that these physicians of the last century often employed antiseptic methods unknowingly?

Cheyne shows there are two prominent methods utilized in the antiseptic treatment of wounds. One, Listerism, or the complete exclusion of all germs from the wound. The other impedes the growth of germs after they have gained entrance to the wound, and this is variously accomplished. Different chemicals may be added to the discharge, rendering it unfavorable for their development, or the secretions may flow away so rapidly that the germs cannot thrive within the wound, or the rapidity may be hastened by flowing water, or by evaporation the fluids may be rendered too concentrated to permit of their growth; or, which seems to apply more particularly to the treatment of the last century, "by keeping the parts at perfect rest, and by operating only when the patient is in good health, the tissues and the blood are in such a state as to resist the development of bacteria in the thin layer of lymph between the cut surfaces, and union by first intention thus occurs. This is best carried out by perfect rest and accurate apposition of the cut surfaces."

Any of these methods are *antiseptic* in the broadest sense of the term. They all tend to impede the growth of germs that have gained entrance to the wound, and only illustrate how well an unknown foe has been contended with. But compared with Listerism, they are rudimentary and imperfect.

A few questions are propounded by the author which I will briefly notice:

"If germs are so easily absorbed by open surfaces and distributed through the system, of what possible use is it to commence the application of antiseptics one or several hours after the reception of a wound?"

Would Dr. Hamilton, if called in a case of poisoning, refuse to give the patient an emetic because some of the poison might have been absorbed by the patient's system? Is it not possible that recovery might take place if the poison remaining in the stomach were removed, and he were prevented from taking more?

Again he asks: "If they only nestle on the surface of the wound, is it not sufficient to apply an antiseptic thoroughly just before closing the wound?" Would it be justifiable for a physician to attend a case of labor with filthy hands, thinking he might syringe all filth away at the conclusion of the labor?

Is there anything irrational in using every precaution in preventing infection?

It is not impossible that Listerism, as now practised, is more complicated than necessary, and in time it may be simplified, and perfected as a system, for it does not claim to be infallible. However, it accomplishes the desired end of excluding all germs more perfectly than any other mode of treatment, and the results are gratifying in the extreme. Any other process which embodies

the same principles is also antiseptic. But we may say, with all confidence, that, so far, no system of treatment, antiseptic or otherwise, has been developed which is not inferior to Listerism. ALFRED C. HAVEN, M.D.

LAKE LOGAN, ILL.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 3, 1886, to January 9, 1886.

MCPARLIN, THOMAS A., Colonel and Surgeon. Now awaiting orders in New York City. Ordered for assignment to duty as Medical Director, Department of the Platte, on January 24, 1886. S. O. 5, A. G. O., January 7, 1886.

GODDARD, CHARLES E., Major and Surgeon. Died at Fort Yates, D. T., January 4, 1886.

MUNN, CURTIS E., Captain and Assistant Surgeon. Ordered from Department of the East to the Department of Columbia. S. O. 4, A. G. O., January 6, 1886.

SHANNON, WILLIAM C., Captain and Assistant Surgeon. Ordered from Department of the Platte to Department of the East. S. O. 4, A. G. O., January 6, 1886.

MCCAW, W. D., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Lyon, Col., and ordered for duty at Fort Leavenworth, Kan. S. O. 1, Department of the Missouri, January 4, 1886.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 9, 1886 :

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

COCAINE AS AN EXTRAORDINARY AID IN SURGICAL OPERATIONS.—Dr. Robert Abbe, of this city, writes: "The value of cocaine as an extraordinary aid in the surgical field is daily demonstrated to the wonderment of all, and I take this early opportunity to notice the extremely satisfactory use of it as a local anæsthetic in such operations as the following: Volkman's method for hydrocele—consisting of a long incision through the scrotum and sac, irrigation of its interior, suturing, and draining—which I have recently done on four patients with cocaine. First, October 7th; second, October 9th; and twice on December 29th, the latter being both double hydroceles. The operations were perfectly painless. Amputation of the scrotum, and ligature of the veins for varicocele, I did under cocaine on October 20th last. The patient said he heard me cutting, but felt nothing—even the suturing at the end of a half-hour was not felt. Twice I have used it in bad cases of Dupuytren's contraction of the hand, namely, December 26, 1885, and January 3, 1886, with most admirable results. Finally, growing bolder with experience, I have twice opened the abdomen under its use. First, in a case of intestinal strangulation at the internal inguinal ring. A very small knuckle had been caught, and gave symptoms without external tumor. I did median laparotomy October 5, 1885, after cocaine hypodermics in the line-precincts of the incision. Second, in a lady of sixty-two years, with a ventral hernia existing twenty-seven years, and being uncontrollable and troublesome, I operated for its radical cure under cocaine. It was a troublesome operation, with extensive adhesions within the sac of intestine and omentum. I opened the sac, reduced its contents, stitched its neck, and closed the ventral ring by five heavy catgut sutures. This occupied over an hour, and the cutaneous anæsthesia was diminished so that the final skin-sutures were noticed, though not in any sense painful to her. Even this could have been avoided if I had chosen to give her a second series of hypodermics half-way in the operation, but she rested so comfortably through it that it was not called for. She had no vomiting to disturb the wound, as she would after ether, and primary union, with a nearly normal temperature, has resulted. That was nine days ago. On January 4th I had the pleasure of assisting Dr. Bangs in operating for the radical cure of inguinal hernia, where the cocainization was absolutely perfect during the half-hour occupied in the operation, and the patient rendered invaluable assistance by voluntary management of the sac. I may say that since the adoption of cocaine ether has been used in less than half the operable cases at St. Luke's Hospital, and bids fair to be still further curtailed."

THE LATE PROFESSOR JOHN C. DRAPER, M.D., LL.D.—At a meeting of the faculty of the Medical Department of the University of the City of New York, held December 23, 1885, the following minute was adopted:

Whereas, This institution has been called upon to bear the serious loss of the removal by death of our distinguished colleague, Professor John C. Draper, M.D., LL.D. Therefore, as an expression of our regard for, and appreciation of, his character, be it

Resolved, That Professor John C. Draper's attainments and services as a man of science in both the departments of Chemistry and Physics, wherein he was not only an able teacher, but also an original investigator, rendered his connection with this college of the highest value to its best interests. The unfailing devotion, also, which he showed for its advancement by the faithful labor of years in the lecture-room and in the laboratories of the college has contributed greatly to its usefulness and efficiency as an educational institution.

Resolved, That the services rendered by him for so many years to this college as its Treasurer must signally testify to his excellent executive ability and command of business methods, as well as to his unselfish readiness to work for the common interests of the institution.

Resolved, That the high character and personal qualities of Professor John C. Draper were specially calculated to secure the esteem and warm attachment of his colleagues. As his clear and sound judgment ever was relied upon for counsel, so also did the genial sincerity of his friendship inspire a confidence which grew with years, and which will cause his loss to be deeply felt and long mourned. CHARLES INSLEE PARDEE, Dean.

PHTHIRIASIS PALPEBRARUM.—Dr. James L. Minor, of Memphis, Tenn., writes: "THE MEDICAL RECORD of December 12, 1885, contains an article by Dr. F. W. Ring, of New York, on 'A Case of Phthiriasis Palpebrarum,' which is reported because of the rarity of the affection—rare in the experience of Dr. Ring—rare in the experience of Dr. David Webster, who has 'been looking for a case of pediculi palpebrarum for thirteen years, during which time he has probably treated over fifty thousand patients'—rare in the records of the Manhattan Eye and Ear Hospital, which show a ratio of one to fifty-seven thousand—and rare in ophthalmological literature. Such an experience is, I am sure, exceptional. During the six years of my connection with the New York Eye and Ear Infirmary, and the two years with the Brooklyn Eye and Ear Hospital, I do not recall a year

when one or more cases of pediculi palpebrarum were not observed. And I find, on referring to the reports of these institutions, that my experience is substantiated. The Annual Report of the New York Eye and Ear Infirmary for 1884 gives eight cases of pediculi palpebrarum out of a total of 11,888 eye-patients treated during the year. The Fifteenth Annual Report of the Brooklyn Eye and Ear Hospital gives thirteen cases of pediculi palpebrarum out of a total of 28,816 eye-patients treated at that institution during the fifteen years of its existence. Here we have 40,704 patients, which furnish twenty-one cases of pediculi palpebrarum, or one case of the latter to 1,938 of the former. This proportion is not too great. In fact, I am not sure that it is not smaller than it should be, for it is far from impossible that cases of *pediculi palpebrarum* should be recorded under the head of *blepharitis marginalis*. I could cite two instances where this has been done by competent observers, during the hurried work of a large clinic. I never considered the cases of pediculi ciliaris which came to my notice as of sufficient importance to report, and that this has probably been the experience of others will possibly account for their paucity in medical literature."

THE SIGNIFICANCE OF A PATULOUS OS.—A correspondent asks us the following question: "Can a virgin or nulliparous married woman have an os uteri sufficiently patulous to admit the tip of the index finger? I have a case of a young woman under my care, twenty-four years of age, strong and healthy, whose occupation for the past eight years was standing at a counter making up packages, and sometimes carrying the same up and down stairs. She consulted me for a slight irritation of cervix. I find the os admits the tip of index finger freely, and the anterior lip is much thicker and harder to the touch than would seem normal, and has a decidedly cartilaginous feel. She admits having masturbated at times some years ago, but denies *in toto* having ever held connections with men, and therefore could not be at any time pregnant. I found the hymen also wanting." [Our correspondent's account of admitting the tip of his finger is too vague to be of any value, and may practically mean nothing whatever. He says nothing about the *depth* to which his digit penetrates. One often feels a cervix in which the conditions seem much as we should judge the cervix was in the case of our correspondent. The whole neck is œdematous, especially the anterior portion, feeling thick, and very much like the "lip." The face of the cervix is flattened, and the finger may seem to be admitted for about a quarter of an inch within the os. The condition described would almost certainly deceive an unpractised finger, and even the experienced touch would require the aid of ocular examination to make a certain diagnosis. Such cases have nearly always acute antiflexion, with more or less enlargement and congestion of the entire organ. Examination by speculum generally reveals evidence, also, in these cases, of a cervical endometritis.—ED.]

THEY WERE DOCTORS.—The cars on an incoming train were filled to overflowing, and a man who got on at a small station walked their whole length without being able to find more than one vacant seat. This was part of a whole seat upon which a single passenger was stretched at length. After standing for a time by this seat, and observing no inclination on the part of the occupant to share it with him, he indignantly exclaimed: "You are an infernal hog, sir." "You call me a hog, sir?" retorted the other, who was instantly on his feet and in a fighting posture. "I'll knock the top of your idiotic head clear across the country, sir." A fight was imminent, when the conductor opportunely appeared on the scene. "Hold on, doctor, what's the matter?" shouted the ticket-puncher. "Doctor?" queried the man from the small station; "are you a doctor?" "Yes, sir." "Why, so am I." "Good gracious! is that so?" and they exchanged cards and shook hands. "Why, of course you can have half my seat—all of it—the whole car." "Oh, no, no, doctor; I wouldn't disturb you for the world." "But, doctor, I insist." "Well, doctor, if you insist, why I'll be glad to sit with you." "Of course, doctor." And the reporter of the *Free Press*, who witnessed the affair, says the two doctors sat down together in one seat, and were so soft and tender and loving that tears sprung to the eyes of every passenger.—*Medical Age*.

STATISTICS OF BLINDNESS, DEAF-MUTISM, AND CRETINISM IN ITALY.—The Italian census of 1881 shows a considerable decrease in the number of blind and deaf-mutes during the past ten years, while the proportion of idiots has slightly increased. In all three affections the number of males affected was considerably greater than that of females, a disproportion which has been found to exist in other countries also. Of the blind the greatest number was found in Calabria, Sicily, and Sardinia, provinces in which most of the inhabitants have dark eyes. This tends to support G. May in his assertion, that the dark-eyed are more prone to blindness than are those with light eyes. The greatest number of deaf-mutes was found in Lombardy. This province and Piedmont contained the largest proportion of idiots and cretins, so that in Italy, as well as elsewhere, the inhabitants of mountainous regions would seem to be more subject to these afflictions than those of the plains.—*Schmidt's Jahrbücher*.

PHYSICIANS' PRESCRIPTIONS AND DRUGGISTS' COMMISSIONS.—Professor A. M. Wilder, M.D., of San Francisco, Cal., writes: "In the number of THE RECORD of October 31st appears a short article entitled "Physicians' Commissions from Druggists." As the article in question is much more damaging to the good name of the profession than to the druggists, it would seem to call for some notice. That certain of the leading prescription druggists give large percentages on the first filling of prescriptions is undoubtedly true, and that there is a goodly number of the leading physicians who accept and receive these commissions is doubtless true. That this is a dishonest practice, and one that cannot be too strongly condemned, is also true. It is simply neither more or less than a deliberate system of robbery, and the commissions thus paid must come from the pockets of the patients. But this charge does not cover, or apply to, all the physicians of San Francisco. There are some who are satisfied with the one fee from the patients (failing to receive which does not cause them to enter into a league with the druggists to garrote them), and the same holds true of some of our best druggists, who positively refuse to give commissions. The statement that "sixty per cent. of *gross receipts*" is given is absurd; this commission is *only* on the first filling of the prescription, and all druggists know how many prescriptions are filled over and over *without* the knowledge of the physician who wrote them; and, as they have the prescription on file, they control the refilling—another great evil and one that has been pregnant with much harm. As high as 66⅔ per cent. is paid here by one druggist on first prescriptions. Is this evil confined to San Francisco? Does it not hold true in every large city of the country?"

THE DIAGNOSIS OF LEAD POISONING.—Dr. Dumoulin recently presented to the Royal Academy of Medicine of Belgium a patient suffering from chronic lead poisoning, upon whom he demonstrated a chemical test for this condition. The man's skin became black wherever it was moistened with a solution of sulphide of sodium or of sulphohydrate of ammonia. This, the speaker stated, supported the view of Pereire, that lead was eliminated by the skin, and also offered a more certain means of diagnosis than did the blue line on the gums.

BREAD FOR THE SCROFULOUS.—Senna recommends the use of sea-water in making bread for children suffering from scrofulous affections. After the dough is mixed it should be allowed to stand several hours before baking. The taste is said not to be disagreeable.

Original Articles.

A CONSIDERATION OF THE THOMSEN SYMPTOM-COMPLEX,[1] WITH REFERENCE TO A NEW FORM OF PARALYSIS AGITANS.

BY ALLAN McLANE HAMILTON, M.D.,

SIR CHARLES BELL, in 1830, under the head of "Affection of the Voluntary Nerves," says: "The most common instance of this is an impediment in speech, when the consent of the muscles is imperfect; but this sometimes extends to all the voluntary muscles of the body. I find that some are capable of lifting a heavy weight, or walking fifteen or twenty miles, and yet they have not the proper command of their limbs; there is an insecurity and want of confidence in the motions of the body, which overtake them upon any excitement; a paralysis of the knees which prevents them from putting one leg before the other, and which endangers their falling. Thus, a gentleman capable of great bodily exertion, on going to hand a lady to the dining-room, will stagger like a drunken man; and in the street any sudden noise or occasion of getting quickly out of the way will cause him to fall down, and in this manner a want of confidence produces a nervous excitement which increases the evil. With confidence, the power of volition acts sufficiently; there is neither defect of speech nor irresolution in the motions of the limbs when the person is at ease or under the flow of spirits."

This is the description of a condition which nearly half a century later was described as a novel disease by a German physician.

In 1876, Dr. Thomsen,[2] the district medical officer of Kappeln, in Schleswig, described a peculiar spasmodic disease of an hereditary character, the victims being members of his own family, and he himself was a sufferer from the malady.

In the year 1866, Leyden,[4] and in 1874 Benedikt,[5] published cases which were undoubtedly of this nature; and later Westphal, Bernhardt, Seeligmüller, Peters, Strumpell; and more lately Schonfeld, Petrone, and Engel have brought forward no less than eight or ten cases. The clinical expressions of the disorder are the following:

1. A sudden spasmodic muscular seizure which attends the performance of a voluntary act.
2. Its subsidence after repetition of the act.
3. An apparent increase in bulk of the several muscles which are chiefly and most frequently the subjects of cramp.
4. An increase in electro-muscular irritability.
5. A normal or slightly excited state of tendinous reflex activity.

These symptoms are often of congenital origin, and progressive as regards intensity. All the voluntary muscles were involved more or less in different cases, but the lower extremities were most often implicated. An attempt to walk was often attended by a sudden flexion of the thigh and leg at an angle of one hundred and twenty degrees, so that the patient presented a peculiar appearance, his body being bent over, and he often fell upon his knees, and when he dropped to the ground he arose with great difficulty. The exercise of volitional efforts seemed only to increase the demoralization. Mental excitement of all kinds made matters worse, and cold aggravated the condition. When the limbs were passively exercised there was resistance and great rigidity.

"If the forearm is rapidly and energetically flexed on the arm, we see the biceps and supinator longus become prominent and hard to the extent that the patient finds it impossible to extend the arm at the moment, the only act possible being one of slow extension which, after a while, finally overcomes the cramp in the flexors" (Petrone).

Vizioli has studied with the dynamograph the action of the voluntary muscles at the time of contraction, at the period of relaxation, and during the continuance of the spasm. When the patient was told to close his fully-open hand, it was at least five seconds before the movement followed. When the fingers were semi-flexed, and the patient was told to entirely close the hand, it was found that the contraction was immediately produced without any volitional retardation.

This contraction was attended by a dynamographic line composed of very marked and numerous oscillations.

It required sometimes five, and even ten seconds for the patient to open his hand after it had been closed a certain time. In this movement the relaxation of the flexors was not marked by a line nearly straight in its descent, but by an oblique line with many oscillations.

The muscles supplied by the cerebral nerves were not exempt. The masseters stiffened, and the patient would stop when eating, his mouth remaining open, he being quite unable to close it. Some patients talked "stiffly," and in Schöenfeld's case the speech was slow and drawling. Some of the patients were unable to open or close their eyes.

Tickling of the palms of the hands, or soles of the feet, would result in flexion of the joint above. In only one case (that of Schöenfeld) were the reflexes exaggerated.

The only American case of Thomsen's disease was reported by Dr. Hugo Engel,[3] of Philadelphia, the patient being a young man seventeen years old, whose symptoms followed a severe fright. Besides the characteristic paresis and rigidity, and the paresis and hypertrophy, there was an increase in the deep reflexes and the appearance of paradoxical contractions, such as Westphal has described.

There seems, in many cases, to be a wide difference not only in the origin of the disease, but in the symptoms associated with the peculiar muscular condition of which I have spoken. In Italy, Vizioli[2] and Ferrari have reported hybrid cases and adult examples like those of Bernhardt, whose patient was a vigorous soldier twenty-two years of age, and Seeligmüller, whose reported case was also an adult male, go to show that a congenital history is by no means the rule.

While there seems to have been a great regularity in the appearance of the symptoms in the several cases already

reported, it must be confessed by those who are at all familiar with the clinical features of many progressive diseases of the nervous system (especially those of spinal origin) that this very trouble which Westphal regards as an anomaly of muscular tonus, is not only an occasional but very frequent symptom of a variety of maladies. In most cases it is purely a psychic disorder which depends first upon inhibitory insufficiency, and secondly, upon an unstable emotional state which interferes with the *origin* of proper volitional mandates. It is an occasional symptom of the third stage of locomotor ataxy, is common in hystero-organic disorders of the nervous system, and is by no means uncommonly associated with coarse cerebral lesions. I therefore do not feel like dignifying this symptom-group, in spite of the fact that it existed in a somewhat definite collection in several members of Thomsen's family.

The cases reported by Thomsen and others show, as a rule, that the appearance of the spasmodic condition is an early one—in this respect resembling pseudo-hypertrophic paralysis. In June, 1885, I saw a boy ten years of age, in whom there was no history of hereditary nervous disease, who presented a condition which in some respects resembled pseudo-hypertrophic paralysis, but like a case reported by Vigoroux, was not. The parents had always noticed some difficulty in the child's movements, and especially a tendency to rigidity. This trouble has increased so that he now walks with the greatest difficulty. He is weakly and looks mentally feeble, and the cranial vault is noticeably low. He is pot-bellied and badly nourished, but there seems to be no special muscular atrophy. The muscles of both calves are hard and enlarged, as are the posterior muscles of the thigh, those of the left perhaps being most noticeably affected. An examination of portions removed failed to show any fatty substitution or increase, and the electrical reactions were normal. An attempt at walking is manifested by spastic and irregular progression, the feet being rigidly forced to the ground, the ball of the foot first coming in contact. The toes are flexed. There is no adduction of the knees such as attends the tetanoid paraplegia of Erb. The child advances in what may be called a squatting position, the knees being flexed so that the legs are beneath the thighs and the body is bent forward. The feet are separated, but there is none of the waddling so peculiar to pseudo-hypertrophic paralysis. After walking in this way for some time, the rigidity, which was very great in the beginning, diminished sensibly, and he did better. The father told me that the patient's arms occasionally became rigid. This child has poor control over the functions of his bladder, but the action of his bowels is unimpaired. His tendinous-reflex activity is apparently lowered. His pupils are both dilated, the left perhaps more than the right. His legs are occasionally slightly anæsthetic for a few minutes. There are times when there is little or no embarrassment in walking, but as a rule his cramps are severe and prompt in their appearance, and are always aggravated when he is worried.

A second case is that of a boy nine years old, in whom the development of the spastic symptoms followed a primary stage of head pain, attacks of vomiting which were cerebral, and some disposition to somnolence. About six weeks before I saw him he suffered an apparent and general loss of power of a higher grade in the upper, and then the lower, extremities, which seemed to be of a volitional character. His inability to move his left arm seemed greatest. When he made any effort the leg or arm became rigid; and when seated and told to raise his foot from the ground his leg became cramped and strongly flexed, so that the middle of the calf was pressed against the chair seat. Attempts at passive extension reveal strong muscular contraction of the flexors. When he is told to use his arm, for the purpose of taking hold of some object, it becomes rigidly flexed. Sometimes when, of his own accord, he makes an effort and the cramp occurs, he will bite his other hand, and it would appear that this vicarious expenditure of nervous energy mitigates the exaggerated muscular activity, for it seems to help him. Within six months he has gained flesh. The muscles of the lower extremities are abnormally developed, and there seems to be a general increase in volume without fat. The rotulian tendon-reflex is, perhaps, slightly increased. He passes his urine frequently, and there seems to be some vesical spasm.

A peculiarity of the case is a certain prominence of both eyes, and something which resembles a lateral nystagmus. His mouth is slightly drawn to the left side, while the tongue points to the right. There appears to be no abnormal electrical reactions. In this case, which presents the loss of power, cramp, and muscular enlargement, there appear to be associated symptoms of complex cerebral disease.

The spasmodic phenomena seem to be associated with conditions of normal or even lowered reflex tendinous activity. In several cases of posterior spinal sclerosis I have seen the same thing, and these are examples:

Mr. G——, well-defined history of syphilis; early history of lightning pains (1881), especially in legs and about arms; sciatic pains; early ocular symptoms; some anæsthesia, especially of right sole, which began one year ago, a feeling as if there was an extra layer of stocking between sole and boot; analgesia and anæsthesia, especially of three outer toes of right foot; patellar tendinous reflex extinct in both legs. When he commences to move in the morning there is great rigidity of lower extremities and sometimes painful flexion of knee-joint. Is for a time utterly helpless, and has fallen repeatedly. His legs, when the seat of cramp, become so rigid and unmanageable that his walk is like that of a marionette. Persistence usually results in an ability to walk naturally.

Fig. 1.—Characteristic Attitude of Patient with Paralysis Agitans. (Strümpell.)

I will now present a case in which this peculiar condition existed in connection with other more familiar symptoms, the patient's malady in many respects resembling Parkinson's disease or paralysis agitans. In at least two cases of the disease of which I am cognizant this element existed. In these cases the trembling was inconsiderable and limited, but the other symptoms, viz., festination, the attitude, the facies, and the piping voice were highly characteristic. The first case is one of my own, the second is reported by Buzzard[1], and they closely resemble each other, and I think we are justified in considering *two* forms of paralysis agitans.[2]

Strümpell[3] also says that he has seen cases of paralysis agitans in which there was little or no tremor, but rather marked muscular stiffening (Muskelsteifigkeit).

Some months ago a gentleman fifty-three years old was brought to me for advice and treatment. His family history was good—his father and mother were free from nervous trouble, but certain relatives of the mother were the victims of mental disease. When a child he had had

1. [illegible] Nervous System.
2. [illegible] Disseminated Sclerosis, [illegible]
3. [illegible] und Therapie der inneren Krankheiten, [illegible]

some cerebral trouble of a hydrocephalic nature. He had always been an active, busy man, supporting a large family and acting in the employ of a large firm, where he managed an important department. About five years ago he noticed a pain in the right ulnar nerve, and especially a dull tenderness over the exposed portion at the elbow. One year after this the pain reached the shoulder, and radiated over the back of the scapula and

downward, and he complained not only of pain at several points over the latter, but in the two outer fingers of the right hand as well. His attention became concentrated upon his right arm to such an extent that, after unsuccessful recourse to liniments and ointments, he kept absolutely quiet, made but few voluntary movements, and was constantly upon the alert to avoid jarring the arm. He really thought of little else, became emotional and hypochondriacal, and gave up his business. He sat constantly in a large chair, and could not arise without the help of some member of his family, though his legs were not paralyzed, contractured, or useless, except in the fact that when he tried to arise they became suddenly and rigidly flexed. The slightest assistance would enable him to arise without the production of spastic rigidity, and this consisted simply in the light touch of a hand, the help being rather an encouragement of confidence than any aid in the way of force.

He presents the appearance of a person suffering from paralysis agitans (see Fig. 2), the condition of general flexion being very marked, the body bowed over, and the chin sunk upon the breast. His face wears the characteristic blank expression. There is little or no festination. His sensibility is good, he has control over his bladder, but he is habitually constipated. Tendinous reflexes normal, cutaneous reflex rather too active, producing peculiar phenomenon to which allusion will subsequently be made. There is a very slight inconstant tremor of the right hand, but this disappears entirely at times, and is not aggravated by efforts at self-control.

The most interesting and peculiar feature of the case is the curious spastic irritability, and its relation to the exercise of will. This is almost universal, but most marked in the knee-joints. At times he walks without effort, at others he cannot stand, because of a sudden immovability and rigidity of the knee-joints, and a general spasm of all the flexor muscles of the thighs and legs, so that he crouches when he attempts to stand (Fig. 3), or falls upon his knees. All attempts upon his part to overcome this are attended by an increase of the helplessness. When he sits with crossed legs he is occasionally seized with a cramp of great violence, and he cries piteously for some one to disengage the limbs. If his arms or legs become the seat of spasm during the performance of some voluntary act, they may retain the position, however awkward, until the attention is distracted. The attempts of bystanders only serve at times to aggravate the rigidity. When his leg is forcibly extended when in the rigid position of extreme flexion, it returns immediately to the original position, suggesting the "penknife" contraction of Westphal. Some time after the particular act is persisted in, its accomplishment occasionally becomes easy, but when startled or worried he seems panic-stricken and utterly helpless.

There is no trouble about swallowing or eating, as a rule, but, occasionally, like some of the reported cases of "Thomsen's disease," he at times cannot shut his mouth. It is occasionally impossible to get him to use his ocular muscles, so that his eyeballs remain immovably fixed, and upon one occasion no amount of persuasion could induce him to change their position.

There seems to be, besides this state of things, a very interesting alteration of the emotions. He has fits of temper when he declares the "devil has possession of him," when he utterly refuses to help himself, and insists upon the entire attention of every member of the family who may be present. Tickling of the plantar surface of either

foot would cause a rigid contraction at the knee-joint. Under the stimulus of excitement or diversion he does not suffer so much. Within half an hour after an attack of complete demoralization, I have seen him kick up his heels and throw about his arms without any trouble or stiffening, and this was done by command of his attendant. Shortly after he relapsed into the old state, declaring his inability to take off his clothes or get into bed, and when no assistance was given he remained in a cramped, uncomfortable position in the middle of the floor for some time. His intellect was unusually clear, and his memory

good. There was not the least suspicion of cerebral softening in this case.

The posterior muscles of the thigh were hard and seemingly slightly enlarged. They responded to electrical stimulation. Moral treatment did some good, and for a time, through the establishment of an improved condition of volitional energy, the patient was enabled to perform acts which had, before treatment, been impossible. The tendency to spasm could not be very greatly reduced, however, and at last accounts there was no substantial improvement.

In Engel's case there was a peculiar symptom to which he is, I think erroneously, inclined to attach little importance. . . . "I noted" (said he), "while inspecting the undressed patient before me, a certain slowness in every action of his, even in his speech and in the lifting of the eyelids, as also in the play of his features; but even these signs have a doubtful importance when we remember that they are often noted in young men of his class." This same slowness was a feature of the case of Mr. X——, as well as of the case reported by Buzzard, and it indicates the abouloimic nature of the trouble.

A NEW OPERATION FOR THE ALLEVIATION OF PERSISTENT DEAFNESS.

By WILLIAM H. BATES, M.D.,

NEW YORK.

Many cases of deafness are not benefited by thorough catarrhal treatment, inflation of the middle ear, the use of Siegle's otoscope, an artificial opening in the drum-membrane, division of the tensor tympani, etc. I desire to call the attention of the profession to an operation which has benefited a number of these obstinate cases.

The operation consisted in puncturing or incising the drum-membrane in from five to ten different places. Simple punctures were made, or the drum membrane was slit in various directions. The operation was repeated as soon as the openings in the drum-membrane had healed. The size and freedom of the incisions must be determined after the first operation for each case.

For the operation I employed a Graefe cataract-knife with a long shank. It is important that the knife be *sharp*, and to make this certain I often used a freshly sharpened knife for each puncture. Pain was avoided by this precaution. A dull knife, or the paracentesis instruments sold in the shops, caused more pain than the patients could bear.

Cocaine was not necessary when the knife-blade was in proper condition, and this remedy would not prevent pain when the knife was dull.

The result of this operation is to leave a number of cicatrices in the drum-membrane; the subsequent contraction of these producing a tension by which the membrane is drawn out. The membrane frees itself from adhesions in this manner, and in many cases loosens the anchylosed ossicles. The various benefits of paracentesis, as formerly employed, are not only obtained but much increased. It is not an improvement the result of a perforation of the drummembrane alone, which, as is well known, is often doubtful and transitory, but the subsequent healing of the openings is part of an improving process. The operation, suggested by that of paracentesis, differs from it in the simultaneous number and extent of the incisions, as well as in the purpose for which it is resorted to, and in the immediate and subsequent results.

Case I.—J. M——, aged fourteen, resident of Boston, presented himself at my office, July 8, 1885. Deaf in right ear since childhood. Has had measles, scarlet fever, and cerebro-spinal meningitis. Has been seen and treated by specialists in Boston. Examination: Drum-membrane depressed, thickened, congested, adherent to the promontory from chronic catarrh of the middle ear, Eustachian tubes congested. Hearing distance for snapping of finger-nails, two inches. Hears no conversation, whisper, or watch. Inflated readily. Hearing distance not improved by inflation.

July 18th.—Thorough treatment of the catarrh with inflation of the middle ear had improved the hearing distance at the outset, but this limited improvement was again lost. In view of the etiology of the ear trouble, and still further from the unsatisfactory result of the routine treatment, and the apparent hopelessness of these cases, even in hands more skilled than mine, I was much discouraged. I then determined to make a paracentesis, but one more general than usual.

July 19th.—I made three incisions in the drum-membrane.

July 20th.—My patient heard better; and on examining the drum-membrane I found my punctures healed, and, while the membrane seemed less congested, it also appeared a little less depressed. With nothing to lose, and perhaps something to gain, I now made bold to make six free incisions into the membrane, hoping for a possible continuation of the improvement. These incisions healed over as rapidly as before; and, on the succeeding days, each day found the hearing improved, with an apparent diminishing depression in the membrane. It now occurred to me that the wounds in healing seemed to draw upon the membrane, and that the cicatrices were acting as elevators.

On July 25th, the membrane having healed, I made a single, but very large incision into the drum, and then proposed to await developments. Daily the hearing improved, until, on August 10th, I found the drum-membrane was healed. Examination revealed that the hearing distance for the watch in the right ear had risen to 18 inches (the same for the left ear), which under favorable surroundings was ten feet.

The patient was seen and kindly examined by Dr. Pomeroy, who recognized the hearing distance for watch at 18 inches. The patient remained under observation until August 16th; improvement had remained and increased. He now returned to his home out of town.

January 13, 1886.—A written communication of this date informed me that the improvement has persisted.

Case II.—N. L. J——, male, aged thirty, merchant, native of United States, came under observation at the time that I had met my first encouragement in Case I.

July 21st.—Began treatment. Complained of noises in both ears, and of constant vertigo. Examination revealed no hearing in left ear. In right ear heard snapping of finger-nails at 2 inches. Drum-membranes depressed, thickened, congested, and adherent to the promontory. Made four free incisions in both drums.

Treatment repeated six times, and on August 9th he passed from observation. On this date the tinnitus was much improved, the vertigo had disappeared. Hearing distance in both ears for snapping of finger nails, 6 inches.

Two months later the improvement was reported as continuing.

Case III.—C. H——, German, aged thirty-four; very nervous man. Complained of noises in both ears. Examined and found to be suffering from chronic catarrh of the middle ear.

October 15th.—Heard watch in right ear, two and one-half inches; nine inches in left ear.

October 16th.—One incision in right drum-membrane.

October 17th.—One incision in right drum-membrane.

October 21st.—No better. Incisions were made in both drum-membranes.

October 29th.—Noise in left ear had stopped entirely. Incision in right drum-membrane.

December 4th.—Noises in right ear a little better. Five incisions were made in the right drum-membrane.

January 11th, 1886.—Incision made in the right drum-membrane.

January 14th.—Three incisions were made in the right drum-membrane.

January 15th.—The noises in the left ear have not returned. The noises in the right ear are very much bet-

ter, and have stopped occasionally. The hearing is better for conversation. Patient appears less nervous.

The succeeding case presents some features of unusual interest. It was in the person of a *deaf-mute*, who seemed intelligent.

CASE IV.—E. R——, female, aged seven [illegible], had scarlatina and measles in early infancy, was never able to speak, but appeared observing and intelligent. Is a fairly developed girl. Has been treated three months at one of our public institutions by a most competent specialist without result. Examination revealed chronic catarrh of the middle ear. The drum-membrane was depressed, thickened, congested, adherent to the promontory.

October 3, 1885.—Began treatment. Hearing distance for the snapping of finger-nails four inches for the right ear, one inch for the left ear. Conversation not heard.

October 4th.—Five incisions were made in both drums.

October 6th.—Both drum-membranes healed. Hearing distance improved.

October 7th.—Four incisions in the right drum-membrane, two incisions in the left.

October 8th.—Hears better.

October 9th.—Three incisions in the right drum-membrane.

October 12th.—One incision in the right drum-membrane. Left drum-membrane not healed.

October 14th.—One incision in the right drum-membrane.

October 15th.—Left drum-membrane healed; incised.

October 17th.—Two incisions in the right drum-membrane.

October 19th.—One incision in the right drum-membrane.

October 20th.—Left drum-membrane incised. Hearing lowered immediately after the operation.

October 22d.—Hears snapping of finger-nails two inches with both ears.

October 29th.—Hears snapping of finger-nails six inches with both ears. Five incisions were made in the left drum-membrane; hearing reduced to two inches.

November 1st.—Right drum-membrane healed. Left drum-membrane open. Hears nails with right ear twenty inches; five inches with left ear. Inflation did not improve.

November 26th.—Hears watch half an inch with both ears.

December 7th.—Three incisions were made in the left drum-membrane.

January 6, 1886.—Three incisions made in the right drum-membrane.

January 11th.—Five incisions were made in the left drum-membrane.

January 13th.—Hears watch at least six inches with both ears. Hears conversation and whisper. Since hearing was restored it became necessary to teach patient language, and she is now, under careful tutelage of her guardian, learning the rudiments of speech, her own name, the names of common objects, etc., etc.

With as yet a limited experience and the comparative brief time which has elapsed since I have first performed this operation, its full scope and range has not yet been determined.

That I have benefited some apparently incurable cases, I can, with becoming modesty, honestly contend. In the light of the classical treatment of chronic cases and its frequent failure, this innovation, which has given results as unexpected and satisfactory to me as to the patients, may be fairly presented for future endorsement. To Dr. O. D. Pomeroy I extend most sincere thanks for kind corroboration as to the hearing of some of the above cases. In conclusion, I beg to state that all of the cases have been seen and examined by observers besides myself.

THE PRESENT ABUSE AND FUTURE USE OF DISINFECTING AGENTS.

By [illegible], M.D.

To differ with the present and to attempt to foretell the future is probably as unhappy a combination as one could well take upon himself. It would make it appear that one was both behind and ahead of the times, either of which is objectionable in scientific matters. There is, however, in almost every field of research, a transition stage that is so mixed up in doubt and "a little learning" that it is less desirable than either that which went before or that which follows after. I do not mean to imply that our knowledge of disinfection is in this stage, but it is not very far from it. No one acquainted with the amount of careful, patient work that has been done in this field would willingly say anything that would detract from its value, and such is not the object of this paper. It is rather an attempt to show that in our eagerness to accept and apply the facts as developed we have overrun the line that marks the boundary between fact and speculation. The usual argument for this is, that it is better to keep on the safe side, but it is not a safe side when one accepts a method based on doubtful theories, and feeling secure in this, neglects other conditions of more certain value. The public have been even less conservative than the profession in matters pertaining to disinfectants, so that their manufacture has become an important part of the great patent-medicine industry. The only difference is that physicians do not hesitate to use and recommend nostrums of this class.

I am satisfied that it is not an overestimate to say that three-fourths of all disinfectants sold to individuals are for use in houses where there is no contagious disease, and in most cases no disease of any kind. What, then, is the object of all this? In the first place, it is to destroy or prevent odors due to lack of cleanliness; and, in the second, to obtain a prophylactic against disease. Occasionally the first of these reasons is a good one, for circumstances may justify it for a time; but when such is the case, it should be remembered that one is simply taking the lesser of two evils, both of which should be done away with as soon as possible, and cleanliness substituted. Under this class of "substitutes for cleanliness" may be included the various water-closet disinfecting machines. Aside from being totally inefficient, so far as destroying organisms is concerned, the fact that they are necessary to prevent odors is the best evidence that the closet or water-supply is not what it should be. If we take away the odor simply, in such cases, there is nothing left to remind us of impending danger.

Unless we could disinfect the air we breathe, and everything we come in contact with, the employment of these agents as prophylactics must be considered as entirely useless. This, of course, does not include their use, as mentioned above, to prevent putrefaction where cleanliness cannot be had, or on material that has been exposed to infectious disease. When we consider the use to which disinfectants are usually put, perhaps it does not matter much that various waste products and useless mother-liquors from manufactories are sold under this name.

When we come to those diseases which are known or thought to be caused by bacteria, there are uses for disinfectants concerning which there can be little or no doubt. For example, the discharges of patients in such cases should by all means be submitted to some effective agent, and such an excess should be used as would leave no doubt concerning its action. Although it is not my intention to treat of individual substances in this article, I think that calcium, or sodium hypochlorite, or concentrated mineral acids, are the only perfectly safe agents when dealing with discharges containing albuminous matter, since complete disintegration of the mass is necessary.

For bedding and clothing, ordinary washing, using boiling water, is all that could be desired. While it would be unsafe to say that nothing is gained by disinfecting the walls, furniture, and other objects in a room not in immediate contact with the patient, there is very little evidence in its favor; and it should never be allowed to take the place of isolation and other precautions. Good ventilation is, undoubtedly, the best means of removing organisms from the atmosphere of a room, and probably, also, from surfaces on which they have been deposited. So little is known, in fact, on this subject of transmission of diseases that any attempt to control it must be based on but little more than guess-work.

While many will consider these views as behind the times, it might be well to wait and see if they are not rather behind the fashion. What is needed is more attention to the sources from which we derive our air, food, and water, instead of attempts to purify them after they have become contaminated; and the hope of the future is not in disinfectants, but in better sanitation.

Aside from these facts, the germicidal and antiseptic value of various substances has not been determined with the accuracy that many seem to think. These values must always remain very far from absolute, and the most that can be said is that they hold under certain conditions which are usually very different from those we have to deal with outside of the laboratory. They are in many cases not even comparatively correct. This is not said to cast discredit on such work, but it simply shows that we know almost nothing about the influence of the various conditions under which our experiments are made. In order that it may not appear that I am alone in finding experiments of this kind unsatisfactory, the following table from the well-known investigations of Palon de la Croix is given. The first column gives the proportion of the substance required to prevent the development of bacteria in fresh meat-juice exposed to the air, while the second column gives the results obtained under exactly similar conditions, except that the culture-fluid had been heated to boiling before the antiseptic was added.

Chloride of lime	1 : 3148	1 : 200
Salicylic acid	1 : 8515	1 : 1250
Potassic permanganate	1 : 2005	1 : 300
Sodium borate	1 : 30	1 : 10

It is evident from this that what would usually be considered a slight change in the culture-fluid not only affects results very greatly, but that it may in one case increase the amount of antiseptic required, and in another diminish it. If we drew our conclusions from experiments made on unboiled meat-juice they would be that the relative value of chloride of lime and borax was about as 100 : 1; but when boiled meat-juice is used, this proportion is changed to about 3 : 1.

What is needed is not an increase in the already enormous number of such determinations, but thorough chemical investigation of the changes that take place when these agents are brought into solution with the various substances present in organic liquids. Progress in this direction must be slow, but it will well repay the labor. Something is already being done in this line by studying the effect of antiseptics on the soluble ferments, where their action is very similar, if not identical to what it is on the organized. For example, I have recently found that salicylic acid, which has usually been supposed to act as a protoplasmic poison, will act on diastase, and even on starch, converting it into sugar, in the same proportion that it prevents the development of bacteria, provided the same conditions, as regards the culture-fluid, are present. Chittenden has also shown that mercuric chloride, and other metallic salts, act in about the same proportion on organized and unorganized ferments. I do not think it possible to find any substance that will prevent the growth of bacteria, and not interfere with the action of the soluble ferments; and if this is true, there is no possibility of administering an agent that will disinfect the alimentary canal, and at the same time prove harmless to the patient, since not only digestion, but most probably many other life-processes, are carried on by means of soluble ferments.

I am not familiar enough with the use of antiseptics in surgery to express any decided opinions as to their value; but for reasons already given it must be considered as very doubtful, except in cases of infectious disease. They at least do good by promoting cleanliness, but this is in part counterbalanced by the harm that sometimes follows the use of poisonous or irritating agents.

In conclusion, it might be well to remember that it has been shown that bacteria do far more good than harm, and it is very probable that we could not live without them, so that in trying so diligently to destroy our enemies we may sometimes include our friends among them.

JOHNS HOPKINS UNIVERSITY,
January, 1886.

A PIECE OF IRIS LIVING IN THE VITREOUS CHAMBER—A NOVEL FOREIGN BODY.

By JULIAN J. CHISOLM, M.D.,

PROFESSOR OF EAR AND EAR DISEASES IN THE UNIVERSITY OF MARYLAND, AND SURGEON-IN-CHIEF OF THE PRESBYTERIAN EAR AND EYE HAVEN HOSPITAL OF BALTIMORE, MD.

G. T. S——, aged fifty-nine, in falling from a height, six months since, received an injury to the right eye. When seen by his family physician, seven hours after the accident, he was suffering intensely, the lids having become very much swollen. Upon carefully separating them a wound was discovered at the upper edge of the cornea, from which protruded a thick splinter of wood. The removal of the piece of wood was accompanied by a bloody, watery discharge from the eyeball, leaving, however, so much clotted blood in the anterior chamber as to conceal the amount of injury done to the eye contents. The treatment pursued was cold applications to the eye, the local use of atropia, and the internal administration of anodynes. As the swelling subsided and the blood-pus absorbed, it was found that sight had been reduced in this eye to light perception only. In time, however, the vision commenced to improve, till after three months large near objects could be again recognized. In the meantime the left good eye indicated some growing impairment of vision, both for distant and near objects, and the spectacles heretofore worn with comfort no longer permitted easy reading. This growing defect in the vision of the good eye was supposed to be a sign of sympathetic complications, and for this reason the patient had been sent to me from his distant home for surgical treatment.

I found the good eye hyperopic $V=\frac{5}{40}$. With a $+2\frac{1}{0}$ lens his distant vision became $\frac{5}{15}$, even above the normal. With a $+\frac{1}{8}$ he could readily read brilliant type. His spectacles were $+1\frac{1}{2}$, four numbers too weak for him, hence his recent annoyance in reading.

At first sight his injured eye presented every appearance of a successful cataract extraction. The iridectomy was large, well-shaped, and centrally located, with clean walls back to the very ciliary border. This well-formed artificial pupil was black, with traces of capsular deposit as seen after successful cataract extractions. He could detect large objects and count fingers readily at some distance from the eye. In putting a $+\frac{1}{8}$ lens before his injured eye I was surprised to find $V=\frac{5}{10}$ and with a $\frac{1}{2}$ $+\frac{1}{8}$ glass he could make out words in brilliant type.

He complained of something moving about in his eye, which seemed to wave before his sight. By oblique illumination I could see a whitish body in the vitreous chamber. An ophthalmoscopic examination showed a healthy fundus and clear vitreous, so as to give a perfect retinal picture. Hanging from the roof of the vitreous chamber, at some little distance behind the thin partial capsular film, was a flap of membrane, apparently

one line wide and two lines in length. It was rectangular in shape, and of a yellowish-white color. Upon its surface could be clearly traced a vessel of some size, starting from the adherent base of the flap and running downward through the whole length of the hanging mass to its very free extremity. This piece of living tissue moved to and fro with corresponding movements of the eyeball.

This floating membrane in the vitreous, adhering to the upper and anterior edge of the choroid, could be nothing else but the missing piece of iris. The splinter of wood in entering the eye-ball through the upper scleral border of the cornea, had pushed a piece cleanly out of the iris, from pupillary opening to ciliary border. This detached piece of iris, still holding on to a broad base, had been pushed back into the vitreous chamber through the suspensory ligament of the lens, having its ciliary body connection partially stripped from its ciliary ligament at this point and thrust back with it. The lens must have been injured also at the time of the accident, because through the torn capsule the aqueous had first caused clouding of lens-substance with loss of vision, and afterward restoration of some sight by its slow but complete disappearance by absorption. As there was a broad base to the flap, with ample nourishing blood-vessels, the piece of displaced iris had continued to live. Although it had been bleached so that all traces of its normal pigment had disappeared from it, yet it was still thick enough to show no translucency. Under ophthalmoscopic examination it stood out boldly as a whitish-yellow membrane against the healthy red choroidal background. Curiously enough, the passage made by the splinter into the vitreous chamber had not been invaded by inflammatory deposits. The hyaloid structures had not become the seat of pathological changes, and therefore excellent vision had been retained to the injured eye.

TWO CASES OF CONGENITAL TORTICOLLIS, WITH REMARKS.

BY B. F. HADRA, M.D.

In October last, when I was living in San Antonio, by a strange coincidence two German mothers (farmers' wives) from the very same settlement, near Austin, consulted me about their babies.

1. Selma W——, a female child, six weeks of age, had a tumor of the size of a small walnut in the middle of the sternal portion of the right sterno-cleido-mastoideus, while the muscle itself was very tense and contracted. The tumor was detected about three weeks previously. The patient was the sixth child of the healthy mother; the birth was easy, without any assistance; head presentation.

2. Helena P——, ten weeks old, a girl, with an identical deformity on the same side, but the tumor larger and more elongated. This girl is also the sixth child of a healthy mother; was born in breech presentation, but without any active assistance. The abnormality was noticed about two weeks after birth, and only accidentally, as happened also in the first case.

These cases were obviously cases of torticollis, and both were operated on by subcutaneous myotomy of the sternal portion, just above the tumors. It was impossible to cut through the muscles in one attempt, so extraordinarily firm were the tissues. The tenotome had to be carried forward and backward several times. Still, I was not perfectly satisfied that I had made a thorough division. Taking, then, into consideration that a cutaneous wound, under antiseptic precautions, could not be of more harm than further subcutaneous manœuvres, and prompted beside by the desire to remove the tumors, in accordance with the wishes of the mothers, I decided to make a cutaneous section, which was done next day with the kind assistance of Drs. Cupples and Kingsley.

In both cases the cut surfaces of the divided muscles presented the appearance of dense cicatricial tissue, the tumors being only enlarged parts of the evenly degenerated muscles, forming nodes in the continuity. There was not a trace of old blood clots, or any discoloration of the neighboring parts. The muscles in both cases were well divided by the previous myotomies, still some fibres of the sheaths were holding the parts at certain points. The tumors, or rather the thickened portions, were removed from the lower ends of the divided muscles, the wounds closed and dressed antiseptically. The children did very well, No. 1 making a recovery per primam, No. 2 having a slight discharge from a little spot which did not heal till two weeks afterward. Both scars are linear and hardly visible. The heads now occupy a normal position, the divided sternal portions are hardly to be detected, while the other portions are more slender than on the opposite side.

The excised parts proved to be throughout fibrous callus, and show under the microscope not a trace of muscular tissue.

Beyond noting the strange coincidence of these cases, both being brought in at the very same time, and from the same settlement, and both being females, each affected on the right side, I would like to say a few words in regard to some points connected with this form of torticollis.

1. In regard to etiology, nearly all authors accept a congenital, or better expressed, a fœtal origin of the contraction. Still, Gross states in his work on surgery: "It has been said to be occasionally congenital, and cases of this description are, no doubt, now and then met with, but they must be extremely rare, none having ever fallen under my observation." Now my cases hardly admit of any other explanation. The tumors are explained in Billroth's "Surgery" (Fischer on "Diseases of the Neck"), following Strohmayer, as "cicatrices in consequence of lacerations of the muscles *during* labor." The ruptures are said to be followed by extravasation of blood, which afterward becomes organized, and Skrzeczka is quoted as having found old blood in three cases within the muscular sheaths. Dolbeau, on the other hand, is quoted as having observed a fœtal inflammation of the sterno-cleido-mastoid muscle. The cases reported herewith possess, then, some clinical value, as the anatomical structure of the tumors and their relation to the muscles were investigated during life. Dolbeau's views are thus confirmed. The children were only a few weeks old when the swellings were first noticed, and only two weeks older when operated upon. If Strohmayer's explanation was correct, some signs of a traumatism should have been found, but, what seems to be of more weight, is that the fibrous degeneration was limited to the point of rupture, and had not extended over the whole length of the sternal portion. Moreover, it is hard to believe that such a solid cicatrix could form in so short a time. The possibility of a traumatism is in my two cases excluded; there was no midwife present, and no manipulations were indulged in. Thus it seems to me that such cases are congenital, and due either to fœtal inflammation, probably caused by traumatism in utero (twisting, etc.), to a want of development of the muscular tissue, or to a heterotopy of fibrous tissue. I will not attempt to decide which is the most probable. Neither will I deny that there may be cases, as reported by Strohmayer and others, of traumatism during labor.

2. Why the right side is predilected, and why, also, the female sex is the favorite, I am at a loss to explain.

3. If the deformity of a congenital torticollis from contraction of the sterno-cleido-mastoid muscles is due to a fibrous degeneration, no orthopædy, no emollient treatment, no massage, etc., will be of any benefit. There is no muscular tissue present and none will form. Of course, I do not speak of torticollis from other causes (rheumatism, spinal malformation, etc.).

4. There is, then, only one treatment, and it is that

recommended by our best authorities, viz., myotomy. The tumors may disappear spontaneously by atrophy without an operation—as it appears from the writings of some surgeons—but the contraction will nevertheless grow worse, if left alone.

5. The question whether subcutaneous or percutaneous operation is preferable, is the last point I wish to make. The subcutaneous operation, it is true, is more elegant and leaves immediately after its performance a smaller external disfiguration. In regard to danger, I see no advantage over the other. Even not taking into consideration the possible injury to the neighboring vessels, it is just as safe to cut down, provided antiseptic measures are taken, as to puncture, and to leave behind a quantity of extravasated blood. In cases in which the surgeon is obliged to withdraw the tenotome and to insert it again, to be sure of having thoroughly divided it, the subcutaneous operation seems to be even more dangerous. The relation of the subcutaneous operation to the percutaneous one is about as aspiration is to incision. But the latter has the following advantages: The certainty of having divided every particle of the muscular band; the ability to remove any adventitious matter that it may be advisable to remove; the avoidance of injury to the many nerves situated on and above the muscles; the facility, finally, of cleansing the wound well and of using perfect antisepsis.

COMPOUND GUNSHOT FRACTURE OF RADIUS FROM WINCHESTER RIFLE, TREATED BY PRIMARY ANTISEPTIC OCCLUSION,

Without Removal of the Primary Dressings until the Case had Resolved Itself into a Simple Fracture with Superficial Ulcerations—With Remarks.

By HENRY I. RAYMOND, A.M., M.D.,

ASSISTANT-SURGEON, U.S. ARMY.

George D——, aged seventeen, a half-breed, was shot through the right forearm by a cartridge of 44 calibre, accidentally discharged from a Winchester rifle which fell from his saddle while his horse was attempting to escape from a hornet's nest.

The lad was forty miles distant from surgical aid, and had to ride twenty-six hours (day and night) over a rough mountain trail, and in the hot summer season (thermometer 93° in the shade), to receive professional care of his wounds. Two large colored kerchiefs saturated with clotted blood had served the double purpose of a provisional hæmostatic and an occlusive covering. On removing these (twenty-six hours subsequent to the injury) an ugly-looking wound of exit—such as would be produced through the diminished velocity of a projectile from fracture of the shaft of the radius—was observable, with pouting lips and torn edges. This wound of exit was two and a half by one and three-fourths inch, extending in the line of the thumb from half an inch above the wrist upward along the radial shaft. The wound of entrance, comparatively insignificant, was situated in the line of the little finger three inches above the wrist. By very gentle manipulation bony crepitus was obtained at the site of injury, and by cautious pronation and supination of the hand no rotation of the head of the radius took place.

The *exterior* of the wounds was cleansed in a bichloride solution, and after drying the surfaces they were dusted over with a powder of iodoform and calomel, and covered with borated cotton and oakum. An anterior and posterior splint were applied with the forearm in semi supination, and the whole secured by adhesive straps and roller-bandages.

The temperature per orem marked 100.2° F.; pulse, 85; respiration, 20.

Considering the ugly aspect of the wound, associated with a compound fracture and of twenty-six hours' standing, it was with some hesitancy that I put to a further test my faith in the efficacy of a primary occlusion, but relying upon the pulse and temperature to signal approaching danger, I occluded the wound, seeking to render the fracture "subcutaneous."

To open up the secretions a purgative dose of blue mass and jalap was administered. Let it be remarked here that this was the only dose of medicine in any form—hypnotic, febrifuge, or pain-killer—that was administered in any shape or manner during the continuance of the case (no indication therefor existing), and the diet was not specially restricted, except that meat was interdicted. The accident of birth was not in his favor, inasmuch as the Indians and half-breeds on this Hoopa Reservation and in the adjoining valleys are scourged with struma, phthisis, and syphilis; hence, whatever of good resulted in the healing process may in my opinion be justly accredited to the exclusion of infecting germs, and the placing of the wound in a condition favorable for repair.

The patient was kept in bed for three days, until it should be determined, from the absence of high temperature, that the wound had not been unsuited for occlusion. He was then permitted to go about the ward and into the outdoor air. On the tenth day from the date of application of the wound-dressings they were removed for the first time, the entrance and exit of the wound-track were dressed as simple ulcers, and the fracture-splints reapplied.

Two days later the patient returned to his home, a distance of thirty miles, by muleback, and made me visits at intervals of about two weeks until, the fracture being consolidated, the splints were removed. The pronation and supination movements of the radius were well preserved, they being executed through three-fourths arc of a semicircle.

Permit me a few lines that are elicited by a criticism which, by some oversight, only to-day met my eye, by your correspondent of October 3d, relating to my article on gunshot wounds in your issue of September 12th.

The above case occurred in my practice while preparing my article of September 12th, and I have related it to show the further practical workings of the occlusive method. I trust my critic, on second thought, will not think me so dogmatic as to recommend or practise "but *one* line of treatment of gunshot wounds." What I wish specially to emphasize is this: That the chief interrogatory to be proposed to one's self, and answered according to the surgeon's best judgment, before proceeding further in a case of gunshot wound, of whatever character, is whether or not the given wound is suitable for occlusion. If it be suitable, and the surgeon, by unclean hands or meddlesome interference, renders it noxious and past occlusion, that surgeon has diminished the chance of his patient's recovery and increased the probabilities of untoward wound accidents. In the case above related, I ask if, in the simplicity of treatment, in the care of the wound, in the shortness of time, or in the securing of beneficial results, any other method would have yielded a better return than primary occlusion? How often would the application of this method in suitable cases do excellent service for the country practitioner, whose busy hours and long drives do not permit him the frequent inspections possible to the city practitioner, should he treat a gunshot wound openly! Primary occlusion takes precedence in every case to which it is applicable. In such a case there is, to my mind, no choice of methods. The occlusive here is the best. In so far, I confess I am somewhat dogmatic. But to assert that no discrimination is to be made in the proper selection of cases for occlusion is farthest from my purpose, and I trust my critic will not impute it to me. I agree with him "that certain wounds require one treatment, while other wounds require other treatment, . . . and this is where a good surgeon is expected to use his judgment, and not merely an antiseptic rag." But, I ask,

upon what is he to base his judgment, unless it is upon certain sound principles of surgical practice which I have endeavored to indicate in my article of September 12th? namely, "If the wound is not a fresh and clean one; if the canal has not been shut off from the external world by shifting of the soft parts immediately that the injury took place; or if the wound track, that has been virtually occluded from the start, is laid open now for the first time by the surgeon's examining finger; or if of necessity the surgeon must go into the wound for the purpose of ligating a bleeding vessel, or of removing some palpable object of infection, *let no such second be overlooked.*" "Insure it a radical disinfection and subsequent complete drainage." On the other hand, if a wound is a fresh and clean one, and virtually occluded when it comes into the hands of the surgeon, let it not become infected and rendered unfit for occlusion through contamination, but let it be immediately shut in from hurtful extraneous influences by a clean (non-septic, antiseptic) occlusive covering, whether it be a simple blood-clot, scab, clean charpie, or an "antiseptic (clean) rag."

An attack was recently made against my advocacy, in a paper read before a county medical society, of occlusion to clean non-infected gunshot wounds, by a surgeon who had served through the Rebellion. In antipode to occlusion, he had known surgeons during the Rebellion to invite maggots to infest their wounds, and those wounds did best that were most strongly beleaguered. I had not advocated occlusion in infected wounds, and in such only do maggots abound. Though necessary evils, they may have served a good purpose in infected wounds; as scavengers they were angels in disguise. Better a filthy city with scavengers; but better still a clean one that needs no scavenging. Better close up a clean, non-infected gunshot wound than to infect it, and then invite scavengers; better invite scavengers than close up one already infected.

As to laparotomy in abdominal wounds, and especially in intestinal wounds, I do not see that my critic takes any issue with my paper, but cites the practice of Dr. Bull, as I also did. The innocuousness of a pint of bloody serum in the abdominal cavity is not so apparent to me, "though, when spread out, would make very little show," inasmuch as the *quality* and not the quantity of a fluid determines its septicity, and the labors of Sims in this direction, as recorded in the British medical journals, are not lightly to be set aside.

Regarding gunshot wounds in general, my attention was recently directed, by Assistant-Surgeon J. O. Skinner, to the remarks of Goodwin in the *British Medical Journal*, February 23, 1884, and to the fact that the German surgeons seem to appreciate the surgical situation very well when they refer to their wounds as "fingered" and "unfingered," and to the very apt remarks of Otis, the surgical historian of the Rebellion, in his reference to the practice of "hermetic sealing," or other innovation of surgical practice—that "an invention, or innovation, is first received with incredulity and unfair criticism, and if these fail of their purpose, then the originality or development of the discovery is questioned."

Fort Gaston, California.

Jubilee of the Finnish Medical Society.—The Medical Society of Finland recently celebrated its fiftieth birthday by a reunion in Helsingfors. The proceedings of the society at this meeting have been published in two large volumes, entitled "Skrifter utgifua af Finska Läkaresällskapet vid dess Femtioaars Fest." The first volume contains an interesting history of the society, written by Dr. Otto E. A. Hjelt, together with a list of the members. Dr. Rosina Heikel enjoys the distinction of being the only female member of the Läkaresällskap. The second volume contains a number of papers presented at the meeting by Drs. Saltzman, Homén, Heinricius, Engström, Holsti, Saelan, Fagerlund, Lindén, and Tigerstedt.

Clinical Department

A NEW METHOD FOR THE REMOVAL OF FOREIGN BODIES FROM THE NOSE.

Dr. D. Bryson Delavan, of New York, sends us the following: "The presence of a foreign body in the nasal cavity is usually attended with marked swelling of the neighboring mucous membrane. Its extraction by any of the means in common use is accompanied with pain, often of great severity, and is often followed by copious hemorrhage. The swelling offers, of course, a serious obstacle to the extrusion of a hard body, while one which has increased in size from the imbibition of water becomes all the more firmly impacted. Hence, in attempting the removal of the body, more or less laceration of the membrane is likely to occur. The pain, with difficulty tolerated by an adult, causes a child to become in almost every instance unmanageable, so that an anæsthetic is required. The hemorrhage is usually controllable after the lapse of a few minutes, but may, meanwhile, cause considerable annoyance. From our knowledge of the physiological action of cocaine upon the nasal mucous membrane, it is evident that, by its use in these cases, all of the above difficulties may be overcome; for applied to the nose, the mucous membrane becomes strongly retracted, the sensibility to pain lost, and the blood-vessels exsanguinated. Thus, the calibre of the fossa is greatly widened, the irritation and consequent resistance done away with, hemorrhage prevented, and the removal of the foreign body thereby greatly facilitated. To carry out the method, the occluded nostril should first be cleansed with a spray or a gentle current of some lukewarm alkaline solution, after which a four per cent. solution of cocaine should be applied to the mucous membrane. When its effect has become complete, the extrusion of the body should be attempted by directing the patient to blow forcibly through the affected nostril. Failing in this, it should be drawn out by some suitable instrument. Should the patient be too restless to make this practicable, an anæsthetic may still be administered. In cases of invasion of the frontal sinus or antrum of Highmore by insects or larvæ, cocaine should be applied to the membrane before the administration of chloroform or ether, in order that the canals leading to these cavities may become as patent as possible, and thus the vapor of the anæsthetic be admitted very thoroughly to the intruder's presence. The insensitiveness of the membrane produced by the cocaine will, in these cases, certainly add to the comfort of the sufferer should it be necessary to inject, or still better, to spray the nose with chloroform."

SYMPTOMS RESULTING FROM SWALLOWING A CATERPILLAR.

Dr. George M. Waters, of Columbus, O., writes: "On November 10th I was called to prescribe for a child seven months old. From the parents I learned that the patient had been in good health previous to 2 P.M., and at that time awoke from a sound sleep with a scream and appeared to be choking. Nothing could be found in the throat to account for these peculiar actions, but considerable redness was noticed about the fauces. At 8 P.M. I found the throat intensely inflamed, a slight elevation of temperature, pulse feeble and rapid, and the patient very restless. The following morning the throat inflammation had subsided, but the temperature had reached 102° F., there were symptoms of intense gastric distress, and the face, body and upper extremities were covered with an eruption resembling a severe case of urticaria. Bismuth and oil were ordered with a mild opiate. On the morning of November 12th, the eruption, with exceptional spots, had disappeared, the temperature had fallen to 99.5°, and there were no indications of pain. The pa-

tient was much better, and well it might be, for with the first free stool was passed the body of a caterpillar an inch and a half long, and larger than the common lead pencil; the hair had been completely stripped from the body, which was complete and covered with mucus. With the two following stools came the brown hair of the caterpillar. This was followed by an inflammatory diarrhœa for three days, when the child began to improve rapidly and is now in good health."

SUPRA-PUBIC ASPIRATION FOR RETENTION OF URINE.

Dr. W. McChesney, of Wauconda, Ill., reports the case of a man, aged sixty-seven, who suffered from stricture, the result of a gonorrhœa contracted some twenty years ago. On attempting to pass water on the evening of June 5th, he was unable to do so, and, getting no relief in the morning, sent for the writer. Repeated efforts were made to pass Nos. 6, 8, and 10 gum catheter, but without success; examination per rectum revealed the presence of a greatly enlarged prostate. Before proceeding to puncture, which operation was considered inevitable, the writer called in consultation Dr. Galloway, of Libertyville, who suggested the administration of chloroform and another attempt at catheterization before puncturing. This was tried without success and the bladder was then punctured above the pubes with a small trocar, about three pints of dark-colored urine being removed.

The canula was retained in position by means of threads attached to strips of adhesive-plaster. "I considered this preferable to repeated tapping with the trocar, as I could see no prospect, immediate at least, for the relief of the retention through the urethra. During the next two weeks the bladder was washed out twice daily with a solution of Squibb's boric acid, two drachms to the pint. This sufficed to keep the organ in a healthy condition, as far as could be judged by the appearance of the urine. I attempted to pass a catheter every other day, but found it impossible to do so. In the meantime the opening into the bladder occupied by the canula had enlarged sufficiently to allow of the introduction of a small drainage-tube, which greatly facilitated the process of irrigation.

"Acting upon the advice of Dr. Muffas, of Wheeling, who saw the patient with me, I now gave large doses of potassium iodide, but as the drug was not tolerated by the stomach it was soon discontinued. After repeated trials of the catheter, with every variety of curve, I discharged my patient. I saw him last week and he is as well as usual. Irrigation with the boric acid solution every other day keeps the urine clear."

THE USE OF COCAINE IN AMPUTATIONS.

Dr. Valentine Mott, of 27 East Twenty-fourth Street, reports the following cases of amputations of the finger in which cocaine was used as a local anæsthetic. They were performed by Prof. Alexander B. Mott, at Bellevue Hospital Medical College, on Wednesday, December 23d. The first case was one of osteosarcoma of the proximal phalanx of the little finger. The patient, John S——, aged twenty-eight, had first noticed the growth about three months ago; it had increased very rapidly, so that at the present time it measured five inches around its largest part. Amputation was decided upon. The patient wished to take ether or chloroform, but the heart was found upon examination to be in such a bad state that it would have been foolhardy to have run the risk. Having administered cocaine in a number of cases of operations for tumor with great success, the writer determined to try its effects in this instance, should the patient be willing. Consent having been obtained, the hand was bandaged tightly at the wrist so as to stop the circulation, and six hypodermics of a four per cent. solution of muriate of cocaine were made along the proposed line of incision and one deep down into the joint. About fifty-five minims were used in all. After waiting ten minutes the bandage was removed and the finger was amputated at the metacarpo phalangeal articulation. The patient said that he *felt absolutely* no pain. The ligation of the blood-vessels, all of which were very much enlarged, took some little time, but during the entire period no complaint was made.

In the second case, which was one of necrosis of the proximal phalanx of the middle finger, the success was not so great, owing in a great measure to the fact that no bandage was applied to arrest the circulation in the part. The patient, Jane G——, married, aged twenty-three, was of exceedingly nervous and excitable temperament. Injections were made as before along the proposed line of incision around the metacarpo-phalangeal joint. No struggles were made by the patient while the finger was being removed, although she said that "it hurt," but upon being questioned afterward, admitted that it did not pain her as much as the introduction of the hypodermic needle, and that the soreness half an hour after the operation was greater than the pain experienced during its performance. In this case about forty minims of the solution were administered. Dr. Mott writes: "In using the muriate of cocaine in similar operations in the future I shall most assuredly apply an Esmarch's bandage, so as to limit the action of the cocaine to the part that is to be operated on; and I have no doubt that, by pursuing this plan and injecting the solution not only hypodermically but deep down onto the sensory nerves themselves, far more formidable amputations could be accomplished with almost absolute painlessness."

HYPODERMIC INJECTIONS OF COLD WATER IN SCIATICA.

Dr. D. H. Lewis, of Lone Pine, Pa., writes that he was consulted by a man sixty years of age, who was suffering greatly from sciatica. He had been treated for the past eight weeks by two physicians, and had run through the entire list of anti-neuralgic remedies. Being desirous of trying something which was at least new to the patient, Dr. Lewis determined to employ hypodermic medication, and, having no drug handy which he cared to use, he filled the syringe with cold water and injected the fluid deep down behind the trochanter. The following day the patient returned and said that he was feeling much better. The injections were accordingly repeated every third or fourth day for a period of three weeks, by the end of which time a complete cure was obtained. The writer has since treated a number of cases of sciatica in the same way, with equally gratifying results. He thinks that possibly many of those cases which have been reported as cured by the injection of certain drugs, such as cocaine, might have terminated in an equally favorable manner had simply cold water been used.

Inoculation with Snake-poison.—It is stated on the authority of Rev. Charles Bixby, a native of the country, that preventive inoculation of snake-poison has been practised in Surinam, Dutch Guiana, for centuries. A snake is caught and teased until the glands secreting the poison are hyperæmic and actively secreting. The reptile is then killed and the glands extracted, dried, and pulverized. The inoculation is practised, usually at the wrist, by causing an abrasion of the skin into which some of the powder is rubbed. It is said that those thus inoculated may suffer themselves to be bitten by the snakes with impunity, for no one who had been properly inoculated was ever known to die or even suffer any ill effects from a snake-bite. This is an item which has been going the rounds of the lay journals, and we by no means wish to vouch for its accuracy.

Progress of Medical Science.

Treatment of Pruritus Ani.—The following mode of treatment of this troublesome affection is recommended in the *Lyon Médical*. After a small enema of warm water, the patient inserts within the anus a tampon of cotton soaked in a mixture of carbolic acid and laudanum, each one part; dilute hydrocyanic acid, ten parts; glycerine, fifteen parts, and distilled water, one hundred and eighty parts. This application is to be renewed from time to time until the pruritus has ceased.

Poisoning by Camphor.—In *The Australian Medical Journal*, October 15, 1885, Dr. J. P. Ryan reports the following case: On the afternoon of September 15th, Miss X—— was brought to his house in a cab, and had to be partly lifted and partly supported indoors. Her hair and dress were disordered, her face duskily suffused and perspiring, the breathing slow, shallow, and with a tendency to sighing, and her pulse was rapid, small, and compressible. Her breath smelt of camphor. She was in a semi-unconscious state, with her eyes partly closed, and if placed in the sitting posture her head and body inclined to fall forward and to the side; but if roused and spoken to loudly, she made an attempt to sit upright, lifted her eyelids for a moment, smiled in a lackadaisical sort of way, and responded rationally, but in the unformed halting accents of a person laboring under the influence of drink. She was above the middle height, strongly built, and her sister, who accompanied her, informed him that she was unusually robust and healthy. They had lunched together at one o'clock on coffee and bread and butter, and afterward were doing some shopping. She had a slight cold, for which she had been recommended to try camphor. She had provided herself with a piece as big as an almond, which she began to chew up and swallow in minute portions. Some twenty minutes afterward she suddenly complained to her sister of feeling giddy and queer, and they had barely time to get into a shop which they were passing when she fell down in a quasi-fainting fit. Resort was had to the usual restoratives—[illegible], cold water, smelling-salts, etc.—and after a little she rallied somewhat, but began to talk excitedly, and endeavored to sing or hum snatches of tunes, paying but little heed to the conversation and efforts of those around her. Her face was flushed, the expression peculiar, and her sister said that only she knew that she never drank any wine or spirits, and that they had been together all the forenoon, she would have come to the conclusion that she was under the influence of drink. As the hilarious excitability was gradually passing into a state of stupor, the sister became alarmed, and had her conveyed to his house. She began eating the camphor at two o'clock; twenty minutes or so afterward she had a quasi-fainting attack, followed by hilarity, excitability, with rapidly ensuing stupor, and when he saw her, about three o'clock, she was nearly unconscious, and in a semi-collapsed state. As her condition was somewhat alarming, he lost no time in giving her an emetic dose, twenty grains of zinc sulphate, which was followed by free vomiting; the vomited matter smelt strongly of camphor, but he failed to find any pieces of the drug in it. After waiting for fifteen minutes, he gave her thirty minims of aromatic spirit of ammonia in a small cup of strong black coffee. Her breathing and circulation improved, her face, from being flushed and dusky had become somewhat pale, the expression being more natural, and she gradually sank into a light slumber. Half an hour afterward he administered another dose of coffee and ammonia, and by four o'clock she was sufficiently recovered to be removed to her own home. She was somewhat light-headed and giddy, but only complained of a burning pain at the pit of the stomach, which had disappeared by the next day. The above case is of interest on account of the severe, if not alarming, symptoms produced by an apparently small dose of camphor. Miss X—— could scarcely have taken more than twenty grains, for her sister, a most intelligent woman, assured Dr. Ryan that the piece was no larger than an ordinary almond. If we bear in mind the slight solubility of camphor in water, it may be fairly assumed that a considerable proportion of this was expelled from the stomach in the vomited matters. Now it follows, if this be granted, that dangerous symptoms of poisoning were produced in a healthy adult woman by a quantity not exceeding the ordinary doses of camphor as given in the principal text-books of Materia Medica.

Spontaneous or Infectious Myelitis.—Dr. Ratimoff related to the Russian Medical Society the case of a railway employee who was taken, after a long walk, with chills and severe pains in the left leg. On admission to the Alexander Hospital the leg was seen to be swollen, the skin was tense and œdematous, and the patient had a high fever with delirium. A superficial incision having given no relief, the tibia was trephined and gave exit to a small amount of pus. After this operation the pain diminished and the temperature fell. But the following day the wrist became painful and an abscess formed. The same thing occurred in the shoulder and at other points, and the man finally succumbed from diarrhœa and prostration. Dr. Ratimoff also reported a second case, occurring in a boy fourteen years old, who was suddenly seized with chills followed by a high fever. The right leg was found to be swollen, and the knee-joint contained fluid. In spite of cold applications, rest, and mercurial ointment, the tumefaction increased and the high temperature continued. The bone was then trephined, a large opening being made to facilitate the exit of pus. The pain at once ceased, the temperature fell, and at the end of two weeks the patient was cured.—*Revista de Medicina y Cirurgia Practicas*, December 7, 1885.

The Ascites of Abdominal Tumors.—The Paris correspondent of the *Medical Times*, November 28, 1885, writes that Professor Terrillon, in the course of some practical remarks on the above subject, said that ascites may be produced in three different conditions: the circulation may be embarrassed locally, as in some varieties of hepatic cirrhosis, or indirectly, as in heart troubles; or the peritoneum itself may be inflamed or irritated, as when associated with abdominal tumors. In the last few years points of differential diagnosis have been elucidated. If the ascites be from obstructed circulation, the liquid will be a limpid fluid, resembling water, perhaps slightly colored, containing a little albumen, but no fibrin, and giving no sediment, containing rarely a few red globules, more often a few small white globules. If the ascites be from peritoneal inflammation, the liquid will be thinner, but never transparent, always cloudy, looking like buttermilk, and smelling like decayed cheese. There is a great deal of albumen in this liquid, and of red cells and large white globules, and it deposits a thick sediment. If the effusion be from simple serous irritation, the liquid will be albuminous, rather clear, and often colored like bile. In the sediment will be found elements of great importance. Besides large white globules full of fatty granulations, large irregular cells may be seen, having a central nucleus surrounded by a quantity of granulations. The presence of these cells is usually taken as the sign of a malignant growth being present. Besides these differential characters, M. Méhu has shown that these liquids do not give the same weight of residue. Twenty per thousand is the rate in the first kind, and forty in the second; in that accompanying ovarian cysts the figure goes up to seventy-five or eighty. One word more on the examination of the liquid: we should not at once conclude on some form of cancer if blood be in it, for we often find it in the simplest forms of irritation. Ascites rarely accompanies simple ovarian tumors. On the other hand, it is very

frequent in external papillomata which irritate the peritoneum. It is also almost always found with malignant tumors, such as sarcoma and cancer of the ovaries, intestines, etc. As a general rule, it may be said that there is no connection between the volume of a tumor and the quantity of the ascites. The books tell of the usual symptoms by which we recognize ascites—the large belly, the sensation of wave-motion from side to side, etc. There are, however, two modes of diagnosis that are not much written about: first, always look for a marked dulness in the lumbar region; second, the vaginal cul-de-sac affords a good chance to detect fluid by a vaginal or rectal examination. This is, indeed, the only way to decide the diagnosis between the ascites and an ovarian cyst. Having detected the ascites, we ask what is the cause of it? There are only three ways to find out. First, examine the abdomen; then puncture, and examine the fluid; finally, make an exploratory incision. If the patient have a great deal of liquid and a small tumor, the physical examination will not reveal much. If there be only a little liquid, there are a few signs that may help; but they are not very sure. Sometimes it is possible to depress the abdominal walls and reach the tumor; there may be a real *ballottement;* and, finally, we may by vaginal examination place the tumor in communication with the abdominal walls, so that we can feel it. These means are not many nor very efficient. In making a puncture with the aspirator, we observe three rules: first, antisepsis of the strictest kind for the trocar and the skin of the patient; second, open the abdomen in the median line, to prevent wounding any large vessel; third, the depth to which the instrument is passed must not be great.

Paralysis Following Tonsillitis.—M. Prevost reports in the *Archives Médicales Belges* for November, 1885, the case of a young army officer whom he was called upon to treat for a sore throat. He was found to have a severe inflammation of the tonsils, accompanied with considerable swelling of the soft palate and neighboring parts, but without any false membrane. Under active treatment the affection subsided in about ten days, but a week or two later paralysis of the right upper extremity appeared. There was no fever, no digestive disturbance; the patient slept well and felt well, and there were no symptoms of cardiac or respiratory trouble. The pupils were regular and responsive to light, no headache was complained of, nor were there any other symptoms of spinal or cerebral disease. After a short period the power returned in the affected arm without the employment of electricity. Dr. Prevost believes that the paralysis was a result of the tonsillitis, and places his case in the category of paresis following simple angina, several instances of which have been collected by Gübler.

Iodoform in Gonorrhœa.—Dr. Oger, in discussing the use of iodoform in gonorrhœa (*Journal de Médicine de Paris*), refers to its employment in solution with glycerine by M. Campana in acute and chronic conditions of the disease. The best results are attained, however, when it is applied to the diseased parts in a very fine powder. In this form Timmermans has obtained excellent results. Iodoform being insoluble in water, he suspends, in two and a half ounces of water, sixty grains of the drug, rendered impalpable by previous solution in sulphuric ether. The mixture being well shaken, a small glass syringe is filled and injection practised. As it is important that the iodoform come in direct contact with the inflamed mucous membrane, the urethra should be thoroughly cleansed by urination immediately before the injection is made. The patient should lie on his back, and the injection be made in a direction nearly vertical, gravity thus causing the powder to seek the lower part of the syringe, and thus favoring its introduction into the urethra when pressure is made upon the piston. When the syringe has been emptied, it should be gently withdrawn, and while the meatus is compressed by one hand, with the other careful pressure is made, so that every part of the passage is reached by the fluid, and the iodoform thus deposited upon the mucous membrane. After four or five minutes the fluid is permitted to escape gradually, in order to avoid the ejection of the iodoform. The operation should be repeated at least three times a day. Whatever is the stage of the disease a prompt result is certain, as is shown by diminution of pain—the iodoform evidently acting as an anæsthetic to the inflamed parts. The character of the pus is also changed, and its abundance diminished. Cure is promptly obtained; in one case resulting in five days.

Intestinal Giddiness.—The existence of this variety of giddiness has long been known to us from the occurrence of that form of it associated with, or caused by, the presence of worms in the intestinal tract. Leube has, however, for many years back noticed another form of it, dependent on flatulent distention and relieved by passage of flatus, and several cases which he has recently observed tend to throw some light on the subject (*Deutsches Archiv für klin. Medicin*). In these, three in number, the giddiness was associated with chronic constipation and relieved by free motion of the bowels or passage of flatus, with the sitting posture aggravated by the act of defecation and relieved by standing or walking, and lastly with intestinal catarrah and flatulence; and in all of them he found on examination *per rectum* that the feelings of giddiness were greatly intensified either by the introduction of the finger into, or its withdrawal from, the rectum. He concludes, therefore, that giddiness in patients suffering from intestinal affections has its source in a diseased condition of the intestinal walls, the sensation being due to pressure on the hemorrhoidal plexus of the sympathetic nerve, but in what way brought about remains yet to be seen.

Baths in the Treatment of Cerebral Rheumatism.—The following are the conclusions formulated by Dr. H. Dupré in a recent thesis on this subject (*Revue Médicale*, December 26, 1885): 1. Hydrotherapy ought to be employed in cases of cerebral rheumatism with hyperpyrexia and delirium, whether the articular symptoms be present or not. 2. The condition of the pulse and temperature, and the nervous symptoms, are the indications to be followed in deciding upon this plan of treatment. 3. In presence of such great danger any temporizing method is inadmissible. 4. Baths are to be preferred to any other plan of treatment. 5. In subacute cerebral rheumatism baths of a temperature of 63° to 75° F. should be used. 6. In the acute form a temperature of 85° to 90° F. is preferable, and this may afterward be reduced, if deemed desirable, by adding cold water. 7. This method is often successful, but it should not be considered as certain, for there are cases in which it occasionally fails. 8. There are no absolute contra-indications to the use of baths, though, of course, the method is not without its dangers; it may give rise to congestions of various kinds, syncope, pleurisy, and the like.

Manifestations of Inherited Syphilis on the Ear.—The two most characteristic lesions of the ear caused by inherited syphilis are, according to Dr. Hermet (*Annales de Derm. et de Syph.*, No. 3, 1885), 1, purulent inflammation of the middle ear, leading to the same local consequences as ordinary inflammation of the same parts, but differing from it in being painless; 2, a form of deafness which is very intense in degree, very sudden in its onset, and in which no appreciable lesion of the conducting apparatus may be discoverable. In a case of this latter kind which is related, deafness was said to have developed in four days, when the patient was nine years old. Dr. Hermet remarks that deafness so sudden and intense could only be due to one of three causes, namely, hysteria, tabes, or inherited syphilis. Hysterical deafness comes on in adolescence or adult life, and its chief feature is its curability. The deafness of tabes is equally

sudden as in the case of syphilis, and attains at least as high a degree of intensity. In the present case, however, the age of the child was against tabes; and at the age of twenty-five, when she was seen by Dr. Hermet, there were no signs of tabes. The diagnosis of inherited syphilis was arrived at chiefly by the history of abortions and early deaths of other children, which was furnished by the patient's mother, who also affirmed that her first husband had spots on the penis at the time of her marriage, and that her second husband told her he had had syphilis in earlier life. The only satisfactory evidence of syphilis in the patient herself was the deafness, which was accompanied by an apparently healthy condition of the conducting parts of the ear. From this case Dr. Hermet draws two conclusions: 1, That in some cases an inherited syphilitic diathesis may be revealed by examination of the auditory apparatus alone; 2, that late inherited syphilis may manifest itself solely by disorder of hearing characterized by complete and absolute deafness of very sudden onset, with integrity of the conducting apparatus. The exact cause of this kind of deafness is not yet known; but it appears to be due to neuritis of the auditory nerve. The affections of the ear mentioned above were the only two which had been observed by Dr. Hermet, in the subjects of inherited syphilis up to the end of 1884, when he diagnosed an ulcerating syphilide of the external auditory canal in a child aged three years.

Diabetes in Children.—Dr. Jules Simon reports several cases of glycosuria occurring in young children, among which is the following (*Revue Medicale*, December 5, 1885). A girl thirteen years of age, had been under treatment for several months for purpura. One day she reported herself as very much better, and little more would have been thought of the case had it not been that, the evening before, Dr. Simon had been reading of a case of diabetes in which the grave symptoms had been preceded for several months by purpura. He was thus led to examine the urine of this patient, and found it to contain sugar in small amount. The girl presented no other symptoms which would even faintly suggest diabetes, and it was only the chance of having read this case the previous evening that led the author to examine the condition of his patient's urine. He suggests that there may possibly be some connection between purpura and the profound alteration which finds expression in saccharine diabetes. The urine contained no albumen and the blood on microscopical examination was found to be normal, at least there was no excess of leucocytes.

Death from Entrance of Air into the Uterine Veins.—Recent observations have demonstrated anew the possibility of the entrance of air through the veins of the uterus from mechanical causes. Olshausen has reported a case in which the uterine douche was employed to bring on labor in a case of twin pregnancy. During the injection, the woman complained of inability to breathe, rose up in bed and fell back dead. Post-mortem examination revealed the presence of air in the coronary arteries of the heart, as well as in the uterine vessels. Another case has been recorded by Litzmann, in which an endeavor was made to induce labor by means of intra-uterine injections of warm water. The douche was employed several times, and, at the fourth, although every precaution was used, the woman suddenly began to breathe with difficulty, the face became cyanosed and death speedily occurred. Here also the autopsy showed that air had entered the uterine veins. On examination of the apparatus employed to make the injections, it was found that the piston did not fit exactly into the cylinder. A third case, related by S. Braun (*Schmidt's Jahrbücher*, No. 2, 1885), shows that air may enter the uterine veins even when there is no external mechanical cause acting. A woman, twenty-five years of age, healthy and strong, pregnant for the second time, was delivered of a healthy infant. Labor was normal, and the presentation was by the occiput. The woman, who had been delivered on the side, was now placed on the back, and the placenta was delivered by expression. Immediately afterward the woman's face became cyanosed, she vomited, had a convulsion and lost consciousness. The uterus was flaccid, and a little dark blood was flowing from the vagina, but in insufficient quantity to account for the collapse. Death speedily supervened. Post-mortem examination revealed the presence of air bubbles in the vessels of the neck, of the heart and of the uterus. Braun explains this occurrence by supposing that, after the placenta was detached, air entered the cavity of the flaccid uterus, and then, some obstruction existing, the pressure of the hand of the midwife forced it into the uterine sinuses. The writer thinks that this may be the cause of collapse, with or without a fatal issue, sometimes observed after delivery.

Splenic Anæmia.—The affection known as Hodgkin's disease is often confounded with splenic leucocythæmia, as there is in both an exaggerated development of the lymphatic ganglionic system, but in the former the characteristic alteration in the blood is wanting. Dr. Banti has described another form of anæmia in which the ganglionic system is unaffected, but in which there is a very noticeable hypertrophy of the spleen. There is no apparent cause for the impoverishment of the blood, as it seems not to be due to either scrofula, rachitis, syphilis, or alcoholism. Climate, sex, and age appear to exercise no causative influence upon the disease. At the autopsy the liver is found to be somewhat enlarged, and of a yellow or brownish-red color. It appears under the microscope to be the seat of a circumlobular interstitial hepatitis, arising from around the branches of the portal vein. The hepatic cells are normal, or are atrophied and the seat of fatty degeneration. The spleen sometimes fills a large part of the abdominal cavity, and may weigh as much as five or six pounds or more. Its color is brownish-red. The capsule seems to be thickened and opaque in certain places. The microscope shows the lesions to consist of an atrophy and sclerosis of the Malpighian corpuscles and of a general sclerotic degeneration of all the network of the organ. The disease begins insidiously and presents, ordinarily, three stages in its evolution. In the first there is hypertrophy of the spleen, which ordinarily passes unperceived; in the second stage the symptoms of anæmia appear; and in the third the cachexia supervenes and leads rather rapidly to a fatal issue. The patient is easily fatigued, his breath is short, and the pulse is forcible and rapid. The skin and external mucous surfaces are pale, and there is often œdema of the lower extremities. Then the symptoms become gradually worse. The skin assumes a dirty-white appearance, the adipose tissue disappears, and the œdema becomes generalized. Finally, come hemorrhages and fever. As secondary symptoms may be noted, hypertrophy of the liver, dyspnœa, dyspepsia, diarrhœa, weakening of the mental faculties, etc. The only treatment advised by Dr. Banti is extirpation of the spleen.—*Journal de Medecine de Paris*, December 6, 1885.

Arsenic with Quinine in the Treatment of Malaria.—Dr. Ernst Hensler, of West Franklin, Ind., warmly advocates combining arsenic and quinine in the treatment of malarial fevers. He says that his residence in the Ohio bottom lands has given him a wide experience in this class of diseases. Like so many other physicians, he formerly used either quinine or arsenic alone, and often without success; but latterly he has been in the habit of giving the two drugs at the same time. Since commencing this practice, he states, all his cases were rapidly cured and no relapse occurred.

Blood-letting in Erysipelas.—Dr. Daniel Lizzaralde, of Buenos Ayres, stated that he has seen most excellent results following the abstraction of blood in facial erysipelas. The procedure is indicated in the case of a strong, full-blooded adult, when the temperature is high and the cerebral symptoms are threatening.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 23, 1886.

MEDICAL-PRACTICE LAWS.

THE Illinois State Board of Health publishes a collection of the decisions which have been given, up to a comparatively recent period, upon medical-practice laws. These are four in number. The first was rendered by Judge E. S. Williams, in the Cook County Circuit Court, Illinois, October, 1878. This decision established the following points:

"1. The State Board of Health, a corporation created by act of Legislature: constituted, among other things, to have charge of medical practice and medical practitioners in Illinois, and surveillance of the professional conduct of physicians in 'the interests of the health and life of the citizens of the State,' in the exercise of its discretion, cannot be controlled by judicial tribunals. 'Unprofessional conduct' and criminal conduct are not synonymous. The law makes the State Board judge of the former. Equity will not interfere to control its judgment.

"2. The law creating the State Board, and that regulating the practice of medicine, are constitutional and valid.

"3. The right to practise medicine is not a constitutional privilege, nor a property, nor a contract, but a mere statutory privilege, subject to the control of the Legislature."

In July, 1884, the Supreme Court of Minnesota gave a decision upon the action of the State Medical Examining Board, which had refused a license to practise to a quack, because he had been guilty of unprofessional and dishonorable conduct. The points are given as follows:

"1. The legislative act of 1883, regulating the practice of medicine, requires as a condition of the right to practise as a physician (except as to those who have been engaged five years in practice in the State) a certificate of qualification from the faculty of the Medical Department of the State University. Section 9 of the act authorizes this board to refuse such certificate to those guilty of 'unprofessional or dishonorable conduct.' The relator was refused a certificate upon the ground that, as the board determined he was guilty of unprofessional and dishonorable conduct: held,

"1. The applicant had a right to be heard upon the investigation as to his conduct.

"2. The word 'unprofessional' in section 9 is used convertably with 'dishonorable,' having a like meaning.

"3. The act is not unconstitutional.

"4. The relator is not entitled to a remedy by mandamus to secure a review of the correctness, or the reversal of the determination of the board."

We have recently learned from Dr. P. H. Millard, of Stillwater, Minn., Secretary of the State Board of Medical Examiners, that the Supreme Court has rendered two further decisions regarding the Minnesota practice law, both supporting its provisions. The first case was that of a man, E. D. Chapman, whose certificate had been revoked by the board on the ground of unprofessional and dishonorable conduct. The report states that "The sole ground of the relator's objection to the provision of the act empowering the board to revoke decisions is, first, that license to practise medicine, when once granted, is property; second, that the revocation of this license is the exercise of judicial power, which cannot be vested in any power but the courts; third, that to vest this power in a board is to deprive a person of his property 'without due process of law.' The radical fallacy in this chain of reasoning is the assumption that such power to revoke is the exercise of judicial power. There is no distinction between granting and revoking such a license; both come under the police power of the State, the object being to exclude the incompetent. All the States empower boards to issue and revoke licenses to dealers, hackmen, pilots, etc. The constitutionality in such cases has repeatedly been sustained."

In the second case, that of E. E. Feller, the report says:

"In the case of E. E. Feller, the ground on which the writ is asked is not the constitutionality of the revoking power, but that the facts stated in the complaint do not constitute 'unprofessional or dishonorable conduct.' The respondent claims that, if true, this is no ground for issuing the writ, at least not until relator had first pleaded to the jurisdiction of the board, and his plea had been denied. The court holds that the complaint is sufficient. Counsel for relator errs in thinking that the only charge is a breach of professional ethics. The complaint sets forth that the relator advertised his ability to speedily cure chronic, nervous, skin, and blood diseases of both sexes; of the eye, the ear, without injurious drugs or hinderance from business, and others specified, well knowing the claims to be false, and intending to impose on the ignorant and credulous. The gist of the charge is not in the advertisement nor its falsity, but that he knew it to be false. If true, this constitutes unprofessional conduct of the grossest kind."

The law of Minnesota, which resembles that of Illinois, is thus supported by three judicial decisions. And the Board of Examiners is able to refuse or revoke licenses on the ground of unprofessional or dishonorable conduct.

The Court of Appeals of West Virginia rendered a decision, in November, 1884, declaring that the medical practice act of that State was constitutional. A similar decision, sustaining the Missouri State Board of Health, has been rendered by the Supreme Court of Missouri.

It seems as though the validity of acts regulating the practice of medicine was established upon a firm ground.

Unfortunately it has happened that, quite recently, an Illinois court has rendered a decision contradictory, in a large measure, to those previously given, and materially abridging, as we are informed, the powers of the State Health Board in regulating medical practice.

MEDICAL ADVERTISING IN THE DAILY PAPERS.

In the name of all that is reasonable and decent, is it not time that there should be an end put to the sensational reports of so-called remarkable operations, as they are now appearing in the daily papers. They mean nothing, and can do no possible good save to ventilate the weak and senseless vanity of men who can obtain notoriety in no other way. Sometimes the operators have nothing to do with the matter, but in the large majority of instances they take care not to object to the appearance of the reports when they are able to do so. The innocent ignorance displayed on their part as to how they were really made is oftentimes a refreshing contemplation for the student of human nature. But to the ordinary professional mind this goes without the saying. Then, again, the real utility of these sensational stories is to be seriously questioned. To the medical profession they mean nothing more than well-written and highly-colored reports of some of the most ordinary work in any of our hospitals. To the public they are especially misleading, even if they are half-way intelligible. In a word, they prove how much the accomplished press-writer can make out of nothing; he, in fact, is the only one who deserves any credit in the affair. He gratifies his ambition in making the article readable. Rhetoric is one thing, however, and practical knowledge of the subject is another matter. Obviously, the remarkable cases are brought before the wrong court. There is a pressing need for a medical clearing-house for the associated press. Not one of the so-called brilliant operations could legitimately claim a two-line item in any respectable medical journal, and yet we see a half-column of solid type in the jealously-guarded space of a leading daily devoted to such foolish recitals as that of removing pieces of dead bone from the leg, and saving the life of the patient thereby, limbering a stiff joint, while the patient was profoundly under ether, doing impossible things with cocaine, and in one case recently brought to the notice of the public, of actually taking a button of bone from the skull for an old depressed fracture! Patients all liable to recover! Think of it. Medicine certainly should be considered a progressive science by the public, and the daring operators who figure in these exploits should be placed at the head of their calling.

The hydrophobia craze is another phase of the sensational in medicine which is just now occupying the attention of the daily journals. Despite everything that has been said concerning the danger of rabies, and the value of inoculation as a preventive, we have yet to see the game before we fire. Hitting a black cat in the dark is not the best way of proving the relation of cause and effect. It is comforting to know that the public is still safe, but God help the poor dog.

We are hearing, too, of many cases of tongue-extirpation for cancer like that from which General Grant suffered. They are supposed to be interesting, not on account of the operation itself (for this is, alas! not an uncommon one), but because General Grant might have been saved by just such a procedure! What a pity if it is true. What a dreadful mistake the medical staff in charge of General Grant evidently made in not thinking of these possibilities before. It is, of course, too late now to ask the question why a few of the daring and brilliant surgeons, who are reported to be curing their cases up to twenty-four hours after the operation, were not called in time. The best men to judge of the character of General Grant's cancer were those in charge of his case, and who bore the responsibility of its treatment. The verdict of professional opinion indorsed their judgment in every particular. The patient himself, who is credited with ordinary judgment and fair discretion, was satisfied, and what is the utility one way or the other in taking out cancerous tongues by wholesale, merely to prove that a similar procedure would have been the best thing for the lamented General.

If surgeons see fit to cut out tongues and reporters take pleasure in heralding these so-called remarkable achievements, the public should at least be spared by the writers the comparisons with cases they know nothing about. These are on a par, as to point and interest, with the usual accounts of the surgical exploits that appear with startling head-lines in some of the dailies.

A CALIFORNIAN'S VIEW OF THE INTERNATIONAL MEDICAL CONGRESS.

We publish below a letter from Dr. A. M. Wilder, Professor of Ophthalmology and Otology in the University of California, and Vice-president of the Section of Otology and Laryngology in the Ninth International Congress.

We can only reiterate here the opinions referred to by Professor Wilder. It would, we are sure, be much better to have the original enlarged committee added to the present Executive Committee. But this would be an almost complete concession on one side and none whatever on the other. As human nature is constituted, it is possibly asking too much. It is right and necessary, however, that the present Executive Committee concede much more than they have as yet done. There is a desire in this city to accept a compromise, which will involve an assurance that the newly added men will have a positive influence in the management of the Congress.

We regret very much to observe that in Philadelphia, although the most eloquent appeals are made for harmony, yet no spirit of concession is shown, and nothing but complete surrender is demanded.

This does not appear to onlookers as a very genuine form of the "loyalty" which is now the pet word with our Quaker brethren.

Professor Wilder writes:

[illegible]

Sir: The most sensible article I have seen in The Record or any other journal, regarding the troubles connected with the proposed Medical Congress of 1887, is the editorial in the number of The Record of December 19, 1885, and is entitled "Measure for Reconciliation." The article in question has the right ring, and should strike a responsive chord in the breast of any one who really desires to have the success of the Congress assured.

It proposes, first, to ignore the quarrels that have existed between the various committees, and to accept the present Executive Committee as the proper body to complete the details, very justly saying that "the profession at large is indifferent to this point, since it feels that this committee would have no right or inclination to oppose

the Congress simply on account of personal disappointment." It very properly demands "equitable representation on a basis that introduces no side issues," and goes on to say that "if the present Executive Committee will now officer its sections on this basis, it will have the full and enthusiastic support of the great mass of the profession and of the medical press."

The Record has made a brave and most honorable effort to bring the factions together, and heal existing difficulties. It drops all controversies, and only demands equitable representation, free from all side issues, the ignoring of which principle by the original committee has been at the bottom of all the trouble.

That, by virtue of geographical position, population, wealth, access to libraries, numbers, easy concentration, and constant opportunities for mental friction upon professional topics, together with the possession of the "open sesame" to the columns of the leading medical press of the country, the large cities of New York, Philadelphia, Boston, Baltimore, etc., should contain a large proportion of the medical writers and teachers of America, and consequently of men more generally known, both at home and abroad, must be patent to all; but that the best practical work in the profession is confined to these large centres is as certainly untrue, and right here the original committee blundered.

If now that portion of the profession who have so persistently denounced the action of the American Medical Association, taken in New Orleans last April, and who have as generally declined to help on the Congress, and resigned the positions assigned to them in the various sections, stand ready to follow the lead of The Record, it behooves the representatives of the great mass of the profession of the country, who are arrayed on the other side, to be equally ready to sacrifice all personalities, and unite on the common basis of making use of the *best means* for securing the *best results*.

With a view to giving this idea a definite form, I would propose that all those who at present hold official positions in the various sections place such positions in the hands of the present Executive Committee, thus giving it the opportunity of making a redistribution of said offices, unhampered and in accord with its best judgment, aided and assisted by suggestions and counsels of the best men in the profession.

As proof of my sincerity in making this proposal, I hereby declare my readiness to place the position I now hold as a Vice-President of the Section of Otology and Laryngology in the hands of the Executive Committee, to be disposed of in accordance with the above expressed views.

Very truly yours,

A. M. Wilder, M.D.

215 Geary Street, San Francisco, Cal., January 5, 1886.

THE TOPICAL USES OF LACTIC ACID.

Professor R. v. Mosetig-Moorhof, of Vienna, has become an ardent advocate of the use of lactic acid in the treatment of certain morbid growths and ulcerations. His earliest results were obtained with lupus, but he has since used the acid with good success in epithelioma, superficial caries, papillomata, and other new-growths.

At a recent meeting of the Royal Society of Physicians of Vienna, Moorhof presented his views again (*Wiener Medic. Wochensch.*, November 28, 1885), and also showed two patients with extensive epithelioma of the face who had been greatly relieved, if not cured, by the acid.

The especial claim made for lactic acid is that it picks out and destroys morbid tissue, while it has very little effect on the surrounding sound structures. It can be applied to the healthy skin for twenty-four hours without producing more than a redness. Lactic acid can take the place of the sharp spoon and is, in most cases, a more searching and thorough agent.

For superficial application to ulcerating or carious surfaces the pure concentrated acid is used. Absorbent cotton soaked in the caustic may be laid upon the affected part and covered with rubber paper. The surrounding healthy tissue can be protected by covering it with the rubber or collodion. The application is left on from six to twelve or twenty-four hours. It is often so painful that the patients cannot tolerate it for the longer periods. After removing and washing, the part is allowed to rest for a day or so, and then the application is renewed.

Moorhof showed patients upon whom he had made twenty and twenty-six applications.

Parenchymatous injections into the pathogenic foci may also be given. In this case watery solutions of the strength of fifty per cent. to seventy per cent. are used, and from six to fifteen minims injected at a time. Several of these injections may be made at one sitting.

Favorable results with lactic acid have been reported in leucopathic buccalis by Dr. Joseph (*Deut. Med. Woch.*, No. 43). It has also been used in laryngeal tuberculosis by Jelinek, of Vienna, and H. Krause, of Berlin (*Berlin. Med. Woch.*, 1885, No. 25). The latter observer speaks well of its properties; the former declares that "it is no specific against laryngeal tuberculosis," a statement which will hardly surprise any one.

The strong organic acids, more particularly the acetic acids, have for a long time been used as caustics against neoplastic growths. The claim that lactic acid has almost specific powers in selecting for destruction only the neoplastic tissue is one that has been made for other caustics, but never substantiated. Whether lactic acid will do any more than acetic, or than chloride of zinc, or the actual cautery, remains still to be seen. Professor Moorhof's endorsement of, and confidence in, this agent is very strong.

PRACTICAL OBSTETRICS IN THE COLLEGE COURSE.

The founding of a Maternity Hospital, connected with the College of Physicians and Surgeons, of this city, marks an era in higher medical education which is worthy of more than a passing notice. It is safe to say that in no branch of medicine has practical education been more needed by the student than in that of obstetrics. The majority of graduates have no opportunities for attending cases of labor until they commence actual practice, and no practitioner goes with more hesitation and misgiving to any of his first cases than to these. All the didactic teaching that is possible in the best-regulated college can never balance the clinical experience in even a single case under the guidance of a practical obstetrician.

Doubtless, many of our readers can recall their first experiences in obstetrics, associated, as they were, with the difficulties of making out the presentations, the possibilities of retained placenta, ruptured perineum, twins, and post-partum hemorrhage. Happy indeed was he who in his first vaginal examination could recognize the

dilating os in the midst of the slippery mucosity of its relaxed surroundings, and happier still he who could go beyond and differentiate at once between the presenting head or the obtrusive buttocks. Most of us were wise enough to leave Nature to herself, and she invariably helped doctor and patient. But the students of this generation will have better opportunities in practical obstetrics than those who are of old. The college and the students are to be congratulated accordingly.

THE PREVENTION OF BALDNESS.

It has been estimated that one-half the adult men of American birth living in our cities are bald-headed. The estimate is not exaggerated, if it is applied to persons above the age of thirty, and it may be rather under the mark. If, now, it be conceded that one-half of our American business and professional men are bald at the present time, it would be interesting to speculate as to the condition of the heads of their descendants some hundreds of years from now. The probabilities point toward a race of hairless Americans, for baldness is extremely liable to be propagated in the male line, and to appear a little earlier in each generation. The American nation is threatened with the catastrophe of a universal alopecia.

It appears to be worth while, therefore, to consider the subject of prevention, since no means have yet been found for the cure. Why are so many men bald before their time?

The answer has almost always been that it is due to the excessive strain and ceaseless mental and physical activity to which American methods of business and modes of living conduce. From the visitors' gallery of the Stock Exchange, for example, one views a mob of shining pates belonging, as a rule, to rather young men.

Any reformer, however, who expects to prevent baldness by changing American habits may as well stop at once, for he will surely fail. Now, there may be, perhaps, help in some other quarter. The sons of prematurely bald fathers should bear in mind that if they wish to save their hair it will only be through industrious attention to their scalp. This much-neglected surface should be thoroughly cleansed at certain intervals. It should be carefully and regularly examined, and if it be unhealthy, dry, and scurvy, the proper applications should be made to it. The wearing of unventilated hats is one of the greatest sources of failure of nutrition of the hair, and these must be avoided. The beard never falls out, because it gets plenty of sunlight and air. These are what the hair of the scalp needs, also. Women are less bald than men, because, for one reason, their scalps are better ventilated. In fine, civilization has made the hair-producing organs of the scalp delicate and feeble. They have to be nursed and cared for, or they atrophy and disappear. Young Americans who do not wish to lose their hair before they are forty must begin to look after their scalps before they are twenty.

MEDICAL TREATMENT.

Dr. Samuel Wilks has recently given vigorous expression to certain of his views upon the subject of "medical treatment." Dr. Wilks is a physician who has attained deserved eminence for his work in pathology and clinical medicine. If he has not always attained the scientific method in his writings, he at least possesses the real spirit of the searcher after truth, and is quick to recognize what is empirical and artificial in medical work.

Naturally the present state of therapeutics does not please him, nor is he in sympathy with the present inordinate zeal displayed in some quarters in behalf of new remedies and novel therapeutical procedures. The physician's duty, as a worker for his profession, is first of all, he thinks, along the lines of anatomy, physiology, and pathology. We have enough drugs already. What we need is a more thorough and profound knowledge of disease. Therapeutics was primarily the daughter of superstition. Disease was once a fetich or demon to be placated by nauseous doses or painful external applications. The people still retain this sentiment and clamor for some medicinal exorcisement. Our art is mainly a weak yielding to this feeling. The doctor has to give drugs, and he is naturally ambitious to do it rationally; hence the vain attempts to erect therapeutics, which Dr. Wilks seems to think is really only fetich worship, into a science.

The proper thing to do, however, is to find out the nature of the disease. When this is done we shall find our remedies at hand. He says: "I think I can show you how an improved treatment has come about, not by the discovery of new drugs, but by a better knowledge of the nature of disease and by clinical observation. Thousands of persons are now cured of epilepsy, paralysis, and various other nerve disorders, by means of iodide of potassium; and why? Because syphilis was found to attack the brain and internal organs when a more extended and closer observation of morbid structures was begun to be made in the post-mortem room. Let me most emphatically dwell upon this fact, that an improved treatment, saving thousands of lives annually, arose, not from the discovery of a new drug, but from work in the dead-house. Suppose phthisis is proved to be of bacillary origin and is to be treated by antiseptics, where are we to look for the origin of the improved treatment? Not to any new remedies, for they were already at hand, but to the pathological laboratory at Berlin. The cold bath has saved many lives in hyperpyrexia. The remedy had always been before us, but was not put in force until suggested by the thermometer. Look, again, at the enormous improvement in surgery due to the antiseptic treatment, whereby tens of thousands of lives are now annually saved. This was not due to the discovery of new remedies, but by seeing the necessity for using those which we had. I might go on illustrating the fact that a very large part of the improved treatment of late years has not been by the use of new drugs, but by pathological and clinical researches, which have pointed out the use to us of those which we have always before us."

Dr. Wilks speaks respectfully of pharmacology, and yet it is easy to see that he has no great confidence in its practical results. Incidentally he gives some rather hard raps to certain favorite drugs. Of strychnia, he says:

"I have seen hundreds, many hundreds, of persons with paralysis take strychnia, and I never remember to have seen it of any service. I should regard it as almost a useless remedy in this disease. On the other hand, it is most valuable in gastric and intestinal weak-

ness, but I am not aware that its administration in these disorders was due to any suggestion of the physiologist.

"Then, again, there is phosphorus; this was a scientific remedy, because the brain contained it, but doomed soon to become ridiculous when the public believed their minds were being invigorated by swallowing zoedone. I never remember seeing more than one patient the better after taking phosphorus, and therefore I am bound to look upon this as a coincidence. In my private pharmacopœa I have attached to the word phosphorus the name 'humbug.'

"Another good example is the use of digitalis in disease, owing to its supposed physiological effects. I have within the last week seen it given in pericarditis, typhoid fever, and pneumonia, in order to lower the rapidity of the pulse, and on different occasions in, I believe, every known disease where the action of the heart is quickened. No remedy at the present time seems more popular among medical men, but I have failed to learn that in a single instance it has had any marked effects. It seems to me, on theoretical principles, not possible that a remedy should act in the manner hoped for, when the rapidity of the heart's movements depends upon so many different causes; the only true way to discover its value is to make clinical observations of its action in the different diseases in which it is administered. The application of a physiological result to morbid processes, to my mind, in this and in many other cases, has been fraught with harm, and I cannot regard the method as truly scientific."

Yet Dr. Wilks admits later, that after a drug has been found practically useful, pharmacological studies may throw light upon its mode of action. Pharmacology, in other words, has its usefulness and scientific merit in illuminating the past rather than in penetrating the future.

The views on medical treatment above outlined are perhaps not particularly novel, but it is well, at times, to be reminded of the precarious footing which therapeutics holds as a science.

The very natural comment will be, however, that, after all, most of our advances in the line of treatment have been under blind empiricism. Pathology did not reveal to us that iodide and mercury cure syphilis, or that arsenic cures neuralgias, or quinine ague, or opium peritonitis. In fact, our art lacks so much of perfection that we can not afford to ignore any legitimate mode of activity that may, by any possibility, advance it. But the wise physician will direct his energies only in those channels in which he is the most likely to attain results. This is the moral of Dr. Wilks' address.

THE "BUSY PRACTITIONER" AND HIS NEEDS.

This individual has of recent years become a very unique personage in the community. The conception formed of him is that he is a capable, hard-working member of the profession, with a large practice among well-to-do people. In addition, he has the usual hospital, dispensary, journalistic, society, and other duties, which so largely make up the routine life of every medical man. He is supposed to have a carefully-selected and well-stocked library, and to take all the journals. In short, he is regarded as the nearest approach to perpetual motion of which the human organism is capable. In view of all these demands upon his time, numerous philanthropic endeavors have been made to construct for him time- and labor-saving devices. Particularly is this true in the domain of literature, and to such an extent has this been carried that it would require every hour out of the twenty-four for him to examine even a tithe of all the books which have been prepared for him. To many a man comes the awful injunction that came to Josiah Allen's wife, "Write a book." He does not, like her, shrink with awe from the task, but boldly plunges into the work. The book is written. If it contains the result of original investigation it is generally dedicated to the medical profession at large. If (as is, alas, too often the case) it is merely a rumination of previously known and accepted ideas, without the reinforcement of any new pabulum, the cud is generally thrown to the "busy practitioner," who wisely lets it remain where it happens to fall. Its final fate is either to slowly oxidize into oblivion or to cause mental dyspepsia in the omnivorous medical student.

The authors of some of these volumes seem virtually to say: "Such a book is needed: this book supplies the need." They remind us of that body o religious believers who once assembled and passed the ollowing resolutions: "*Resolved*, that the saints shall inherit the earth: *Resolved*, that we are the sain' " nd then adjourned *sine die*. It is not recorded that these resolutions ever produced any vital effect upon theology at large.

The busy practitioner is not blind to his own best interests. Such abstracts for ready reference as he may need from general medical literature he prefers to make for himself. If he cannot find time to do this, he should narrow the circles of his duties to that point where he can acquire that indispensable knowledge which will enable him to keep up with the times. He is not harmed by the books of the class to which we have referred. They fall into the hands of students, who make a wrong use of them. Our best, well-rounded students are not those who rely on abstracts and condensations, but those who follow a wide course of reading, centred around original thought and wide experience. In so doing they plough a wider and deeper furrow. Once emancipated from the confining influences of college examinations they press steadily forward, choose the more solid and practical works, and become our independent thinkers.

Above all, clinical facts are always valuable. We have thus far been able to solve but comparatively few of the problems of medical science. Any data bearing on these problems are most welcome, but in view of the present crowded condition of our literature it is a solemn thing to add mere duplicates of what already exists, without adding any new material. The burden is already heavy enough.

The Health Officer of the Port of New York.—The term of the present Health Officer expired some time ago, and it is only because a "deal" could not be made that he or his successor has not been appointed. Among the persons who are now reported to be aspirants for the position are Drs. F. R. S. Drake, Charles Phelps, A. Flint, J. C. Hutchinson, T. S. Bahan, and L. Foster.

News of the Week.

A Maternity Hospital for the College of Physicians and Surgeons, New York.—Mr. William Douglas Sloane, of this city, is about to erect at his own expense, for the College of Physicians and Surgeons, upon their land, Fifty-ninth Street and Tenth Avenue, a Maternity Hospital. His wife, daughter of the late W. H. Vanderbilt, has endowed the hospital, so that all its beds will be free. When completed, the hospital is to be given to the College. It will bear the name of the "Sloane Maternity."

The American Journal of Obstetrics.—The erroneous impression has reached the profession that *The Journal of Obstetrics* has discontinued the department of Diseases of Children. This is by no means the case. The department of Diseases of Children has merely been discontinued as a *separate* feature of the journal, and has been returned from the care of a special subeditor to that of the editor-in-chief, Dr. Paul F. Mundé, to whom all contributions relating to pediatrics should be sent.

The Massachusetts Board of Health.—A committee from the Massachusetts Medical Society, consisting of six physicians, has been appointed to urge upon the Legislature the advisability of the reorganization of the Massachusetts State Board of Health, by separating it from the Board of Lunacy and Charity.

Our Esteemed Contemporary, the *Florida Medical and Surgical Journal*, is a vivacious and interesting exchange, with no foolish bias in favor of metropolitan medical centres, especially New York. It should not, however, forget that even the lost children of cities larger than Jacksonville have their rights, and we beg of it, when quoting our editorials, to give us the credit, not the *Weekly Medical Review*.

Successful Enforcement of the Medical Law.—With the morning of a new year comes the dawn of better days for the medical men in California. Within the last few months several irregular practitioners have been arrested and brought to justice.—*Pacific Medical and Surgical Journal.*

New York Pathological Society.—It is rumored that the Pathological Society is shortly to come into the possession of funds which will enable it to found a lectureship.

We are pained to see that the *Medical and Surgical Reporter* is departing from its usual conservative and straightforward methods in order to misrepresent the status and statements of The Medical Record. Quoting only a portion of our editorial of January 9th, in which we published the letter of Dr. Johnston, of Paris, it makes us say that "a considerable part of the best men of the profession have been excluded from the International Congress." Our contemporary must know that this is not the whole of the sentence, and it misrepresents our meaning when thus quoted alone. We are forced to add further, that our esteemed contemporary appears to have forgotten that the management of the proposed Congress is not now in the hands of the American Medical Association, but in those of an Executive Committee which has declared itself entirely irresponsible of that body. Appeals to the "loyalty" toward the Association, therefore, are simply a process of beating the wind. Finally, our ever-welcome contemporary should know that italics and small caps cannot make an inherently weak argument vigorous. The *Reporter* is unjust in attributing to us motives of action which do not exist. It is unfair, we think, to its readers in giving them a distorted history of the present status of medical feeling as regards the Congress.

Bellevue Hospital and the City Morgue.—The annual statistical report of Bellevue Hospital, for 1885, shows that during the year 11,864 patients were treated in that institution. Of that number 1,106 died. There were 585 patients in the hospital on January 1st. The year's record at the Morgue shows that 5,763 bodies were received there, 3,967 were buried in the City Cemetery, and 82 bodies were unidentified.

The Erie County Medical Society has been enforcing the medical law, and recently caused the arrest of "the veteran phrenologist," O. S. Fowler, for practising medicine without a license.

The other Side of the Case.—While the Drs. Purdy were fined $500 for reporting a case of small-pox, we learn that now Dr. Z. P. Dendler, of Long Island City, has been indicted and held on the charge of not reporting a case of small-pox. Verily, the doctor's position is not a pleasant one.

Testimonial to a Retired Physician.—A movement is on foot to give Professor Tröltsch, the very distinguished aurist of Vienna, a presentation in recognition of services rendered to science and the medical profession. He has for some time been unable to practise, owing to ill-health, and it is proposed to give him a sum of money, accompanied by an address and an album containing the photographs of those interested in his welfare.

Honoring the Memory of a Physician.—The *Maryland Medical Journal* gives an interesting account of the character of the late Dr. William M. A. Maxwell, of Kent County, Md., and says that "during the month of May last a number of citizens of the county assembled, and, after adopting resolutions expressive of their high regard for the deceased and their deep sympathy for his bereaved family, decided to erect a monument as a token of their love for him, and as an indication of their appreciation of his excellence and usefulness as a citizen, physician, and friend. A committee was appointed, and by June 1st $718.25 had been subscribed for this purpose. On December 22d this monument was unveiled, and an able address was delivered by the President of Delaware College, of which Dr. Maxwell was an alumnus, reviewing the life and character of the deceased." The record of such an appreciative deed ought to be a help and stimulus to all who love their profession.

A Fundamental Objection to the Pneumatic Cabinet.—Dr. H. P. Chace, of Highland Falls, N. Y., writes: In connection with the subject of treatment of lung diseases by pneumatic differentiation, which is so ably presented in theory, at least, in last week's issue of The Medical Record, I wish to say that if there is any benefit to

be desired from its use it is practically excluded from the large majority of sufferers from lung troubles, by the enormous rental (two hundred and fifty dollars per annum !) asked for these instruments. Not one country practitioner in twenty can afford to use one. In the first place, a country physician has but comparatively few patients with chronic lung disease to treat each year. The aggregate of the cases seen by the country physicians form the large majority of those afflicted with these diseases, but they are widely distributed, and not a great number come to any one physician. Again, many of these can only pay a small fee to the doctor. You can't draw blood from a stone; if a patient has not the means, you can't get from him a large sum for treatment. To be sure, the authors explain this enormous rental under the very high-sounding phrase of "keeping them (the cabinet) out of the hands of unscrupulous men," but the same policy will keep it out of the hands of professional men.

Stephen Smith's Amputation at the Knee-joint.—At a recent meeting of the Royal Medical and Chirurgical Society, London, Mr. Thomas Bryant read a paper on amputation at the knee-joint, and reported thirty cases. The author strongly advocated disarticulation by the method of Dr. Stephen Smith. He exhibited illustrations of the operation, and indorsed completely the remarks of the American surgeon upon the value of his method of procedure, and strongly urged its application to cases of amputation in the leg also. The muscle substance was generally included in the flap in thin subjects, but not in others. The resultant stumps in the leg thereby obtained were excellent. As compared with other methods mentioned, Mr. Bryant stated that the method of Dr. Stephen Smith was to be preferred, as it gave a better covering to the condyles of the femur, and the flaps were less prone to slough; it also placed the cicatrix entirely behind the condyles, out of the way of injury, permitting no bagging of fluids, the stump being in the best position for drainage.—*Lancet*, Dec. 12, 1885.

No Increase in Medical Schools and Students during 1885.—In a pamphlet recently issued by the Illinois State Board of Health, entitled "Medical Education and Medical Colleges in the United States and Canada, 1765–1885," it is stated that the most suggestive facts revealed by a study of the tables and data presented are: First, that the number of medical colleges has not increased during the past year; second, that the number of medical students and of medical graduates are decreasing. There are still 128 institutions for medical instruction in the United States and Canada, the same aggregate as at the date of the last report. But there were 760 less students in attendance upon, and 273 less graduates from, the sessions of 1884–85 than upon and from the sessions of 1883–84. In the United States there were 953 less students, and 278 less graduates. In Canada there were 176 more students, and 5 more graduates. Third, a more marked uniformity in the requirements of colleges. There are two more regular schools (101), the same number of homœopathic (13), one less eclectic (11), and one less physio-medical (1), which with two miscellaneous or mixed schools, make the aggregate (128) as before. The number of medical students in 1882–83 was 13,088; in 1883–84, 12,762; in 1884–85, 12,002. In 1881–82 there were graduated 4,555; in 1882–83, 4,215; in 1883–84, 4,101; in 1884–85, only 3,831. This is not very pleasant news for the colleges, but it is very comforting to the general practitioner who is now fighting for a livelihood. The decrease in students and graduates has affected eclectic schools the most, homœopathic schools next, and regular schools least of all, another fact which is encouraging. The increase in past years in students is most conspicuous in the smaller provincial schools, while in the large cities—Boston, New York, Philadelphia, Baltimore, Cincinnati, Chicago, New Orleans, and St. Louis—there has generally been a decrease. Thus the number of matriculants in medical schools in New York has fallen from 2,209 in 1880–81 to 1,826 in 1884–85. This fact will probably be interpreted in two ways, according to the point of view of the observer. It may mean that the metropolitan schools are getting more rigid in their requirements, or that the provincial schools are getting to be better educational institutions. In our opinion both factors are at work.

Attitude of the Philadelphia County Medical Society toward the International Medical Congress.—The Philadelphia County Medical Society held its annual meeting on the 6th inst., for the election of officers and delegates to the State Medical Society and American Medical Association. The regular ticket was set aside and a new one elected by a large majority. The following resolutions were presented by Dr. D. Hays Agnew, and adopted:

"*Resolved*, That at its annual election of delegates to the American Medical Association and to the State Medical Society the Philadelphia County Medical Society desires to express its regret at the action of the American Medical Association at New Orleans, in view of the injurious results which followed to professional harmony and to the prospects of the International Congress.

"*Resolved*, That the delegates from this Society be instructed to endeavor to secure such modification of that action as may best conduce to the re-establishment of professional harmony and to the success of the Congress."

"The Sun" Remedy for Hydrophobia.—*The Sun* is generally brilliant in its eccentricities, but it is now doing a curious thing in publishing from time to time what it calls "Dr. Toal's Remedy for Hydrophobia," as follows: "Wound to be cauterized with strong nitric acid, and then dressed with one-half drachm of belladonna ointment and seven and a half drachms of resin. In the case of an adult the following internal remedy is to be taken: ℞. Kali iodid., ʒ iij.; tinct. cinchona, ℥ ij.; syrup simplex, ℥ iv. One tablespoonful after each meal. For children from one to seven years old, half a teaspoonful is a sufficient dose, and for children from seven to twelve years old, from one to two teaspoonfuls. Putting it in other words, two to five grains for a child under seven, and five grains for one under twelve years. This treatment is to be followed for one week, even when the dog is not mad, as the virus of an angry dog produces hydrophobia. When rabies is manifest, the treatment is to be continued for three weeks. In such a case the fluid can be injected with good effect in doses of from fifteen to thirty grains every two hours."

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MATERIA MEDICA AND THERAPEUTICS.

Stated Meeting, Wednesday, December 16, 1885.

JOHN C. PETERS, M.D., CHAIRMAN.

THIS Section was fully organized on Wednesday evening, December 16, 1885; Dr. John C. Peters was elected Chairman, and Dr. R. W. Amidon, Secretary.

Dr. PETERS then, by special request, read a paper on

THE TREATMENT OF CHRONIC RHEUMATISM.

He merely alluded to chronic rheumatisms of the heart, pleura, membranes of the brain and spinal cord, of the eye, ear, throat, kidneys, uterus, etc., and quickly turned his attention to chronic rheumatisms of the joints.

Almost all rheumatisms are connected with an excessively acid condition of many of the secretions and excretions, including the saliva, perspiration, and urine; even the chyme and blood are less alkaline than they should be. Next is the excessive preponderance of fibrin in the blood, and the great and early destruction of red blood-globules.

Alkalies form the natural basis of the treatment of almost all rheumatisms, and the first question which arises is whether the potash or soda salts shall be used, or both. As the phosphates and potash salts naturally predominate in the red corpuscles and in the formed tissues, while the chlorides and soda salts are most abundant in the serum and plasma, and in all the infiltrating fluids of all the organs of the body, both potash and soda may have to be used; and they will so aid and compensate each other that neither will have to be given in excess. In chronic rheumatisms Dr. Peters preferred the milder and more tonic soda and potash salts, such as the phosphate of soda, etc. This is a good and mild laxative when purgatives are required; it also lessens the acidity of the mouth, stomach, and bowels which is apt to be present, renders the contents of the thoracic duct and the blood more alkaline, and makes the urine and perspiration alkaline. It also lessens the quantity of fibrin in the blood. It is a cooling and slightly antipyretic remedy, and may be used in strong or saturated solution as a local application to chronically swollen joints. In chronic arthritic rheumatism Charcot prefers the carbonate of soda, of which he gives from seven to ten drachms a day, even to old and feeble women, and says he has never seen anæmia or any dissolution of the blood caused by it; on the contrary, his patients even grew stouter and stronger, possibly from the better digestion of sugar, starch, and fat which is caused by this and other alkalies. It also aids in the destruction of an excess of fibrin in the blood, and helps the liver in its great work of destroying fibrin.

Phosphate of soda is a gentle and pleasant remedy, which may be given in about the way that citrate of potash and Rochelle salts are usually given; the latter in half or one ounce doses when laxation is required, and either in one or two drachm doses when their alkaline effects are more desired. It neutralizes all acids, even that which is abnormally present low down in the large bowels; and moderates the excessive acidity of the normal acid phosphate of soda in the urine, and then helps to keep uric acid and the other urates in solution.

But potash is the natural alkali of the red blood-globules, of the muscles, fibres, and all other formed and solid tissues; and citrate of potash, and even Rochelle salts, which is a tartrate of soda and potash, may reach not only the serum of the blood, but the blood-globules and the parenchymatous structures, when rheumatism is firmly lodged in the latter.

Benzoate of soda is another non depressing soda salt, although it is somewhat antipyretic when given in large doses. It is a solvent of uric acid, increases the elimination of urates in rheumatic lithiasis, and seems not only to convert uric acid into hippuric, but also to liberate a portion of the products of disassimilation in the form of soluble hippuric acid instead of insoluble uric. In delicate and sensitive patients benzoate of soda may be given with aromatic spirits of ammonia, thus: Sodii benzoatis, ʒ vj.; spts. ammon. aromat., ʒ vj.; spts. myristicæ, ʒ vj.; spts. chloroformi, ʒ ij.; spts. gaultheria, ad ℥ vj.—dose, ʒ j. to ʒ ij. in water.

The hippurate of soda has been suggested lately in doses of five to thirty grains. It tends to produce soluble urates. A favorite prescription with Granville is: Sodii hippuratis, ʒ ij.; glycerini, ʒ vj.; aq. cinnamomi, ad ℥ vj.—dose, ʒ ij. to ʒ viij. three times a day.

The tauro-cholate of soda also holds uric acid in solution, and is said to render the stools characteristically rich in bile without causing purging. The usual dose is three to six grains, and it is said to be most useful in obese rheumatic patients, in whom the excess of fat slowly melts away. It is doubtful whether it is more useful than purified ox-gall.

The salicylate of soda is only useful in the acute aggravations of chronic rheumatism. It does not destroy the rheumatic element in the blood.

Valerianate of soda is declared by Granville to be very useful in weak and very sensitive patients. He even thinks its therapeutic value is decidedly greater than that of most of the other salts of soda. It relieves the nervous trouble and hyperæsthesia of rheumatism and gout quite effectively, and he cannot help thinking that it also promotes the activity of the absorbents, thus tending to remove congestion, exudation, and even thickening and hardening about rheumatic joints. Usual dose, one to five grains.

It may be assumed that all the good that can be got out of soda will be obtained by these preparations. Charcot always gives quinine, also, when he uses soda or potash in large and long-continued doses. Others prefer salicine as an anti-rheumatic tonic. Both prevent the excessive formation of uric acid. But the tartrate of potash and iron is the best tonic against the anæmia and debility of chronic rheumatism. It is pleasanter and better than the muriate tincture.

But, as before said, the soda salts only reach the liver and pancreas, the intestinal juices, the chyle and serum of the blood. They do not penetrate into the interior of the red blood-globules, nor into the parenchyma of the muscles and fibrous tissues, which the potash salts do. The acetate of potash, quickly supported by iron, is a most valuable remedy in subacute rheumatism, and especially in those forms which are liable to frequent acute exacerbations.

But citrate of potash is a much more pleasant and less depressing remedy in very chronic cases.

There are, pathologically, two great varieties of chronic rheumatic joint disease: 1, the fibrous; 2, the dendritic. In the fibrous form the tendency of all the exudations is fibrogenous. The inflammatory products or thickenings, instead of remaining in the soft and gelatinous stage of fungoid granulation, become firm and tough. The new cells are converted into fibres, and these harden and contract; even the inner surface of the synovial membrane is made hard. The normal dendritic growths of the villi are conspicuously absent, and in place of them are thick folds of fibrous tissue. The synovial membrane itself is infiltrated with fibrinous substance, composed entirely of fibre-cells, both fusiform and oval; only a few round cells are to be seen.

The favorite remedy for this state is the muriate of ammonia, administered as freely as iodine of potash is often given. If fears are entertained that it will prove too debilitating, it may be aided by aromatic spirits of ammonia, or with quinine, or Huxham's tincture of bark; although Granville prefers the tincture of serpentaria,

which he thinks has a specific effect. The muriate tincture of iron should not be forgotten.

Muriate of ammonia is a solvent and liquefacient remedy which tends to render all the secretions more abundant, while at the same time it reduces the plasticity of the blood and destroys fibrin.

It acts upon the kidneys, and if long continued will cause emaciation, commencing first with absorption of fats and then of soft fibrin. It is used both internally and locally against fibrous thickening of the ligaments and tendons about rheumatic joints. Some go so far as to think it almost specific against all cirrhotic affections of the connective tissues. In chronic rheumatic synovitis it is said to break down all the exudations into a thin mucoid substance which is finally absorbed. It also has a powerful effect on the formation of urea; it is not only converted into urea, but helps to break down uric acid into urea, and aids in the excretion of both. It is also supposed to be really useful in so-called rheumatic neuralgias, when the fibrous sheaths of the nerves are involved. The dose is from five to fifteen grains up to one hundred and fifty grains a day.

Its great rival is corrosive sublimate, which may be given in doses of one-twenty-fourth to one-sixteenth or more of a grain, in Huxham's tincture of bark, or in the tincture of serpentaria.

The next great variety of chronic rheumatic arthritis, or synovitis, is the dendritic, in which the folds or fringes of the synovial membrane are greatly developed, so as to nearly resemble papillomata. For this sabina has been suggested, especially when it occurs in females at the menopause, or where there is decided uterine derangement. Sabina once had a great repute, which was not undeserved, in chronic rheumatism and gout, for which it was employed both internally and locally to the affected joints.

Pulsatilla is a remedy which is supposed to act specifically upon almost all the mucous and synovial membranes, especially those of the small joints, and has a well-assured reputation in chronic rheumatism. It is most useful in subacute and chronic arthritic rheumatism when there is little or no fever; also in what is called rheumatic gout in females, with catarrhal and rheumatic disorders of menstruation.

But next to carbonate of soda, Charcot prefers iodine to the muriate of ammonia and sabina; not iodide of potash, but tincture of iodine, in doses steadily increased from eight to ten drops in twenty-four hours up to thirty to sixty drops. He gives it during meals in water slightly sweetened, or in a glass of Spanish wine, which he says is better. He continues it for several weeks, or even months, and says it never gives rise to symptoms of iodine poisoning. Probably its effects are largely counteracted by the starch in the food. Granville also thinks iodine the most potent and suitable medicine to decompose urates in the blood, and says it relieves chronic rheumatic pains so promptly that he has rarely to use anodynes. But he always gives it combined with muriate of ammonia and chlorate of potash, thus: Ammonii chloridi, ℥ ss.; potassæ chloratis, ʒ ij.; tinct. iodii, ʒ ij.; glycerini, ℥ ss.; aq., ad ℥ xij.—dose, from a tea to a tablespoonful two or three times a day. The taste of this mixture is more disagreeable than that of the tincture of iodine. One of the best prescriptions is that of Dr. Buckler, viz.: Iod. potass., gr. ij.; iodid. ferri, gr. j.; iodine, gr. $\frac{1}{10}$; ext. conii mac., gr. j.—make one pill, to be taken three times a day. These pills are easily taken, and are said to be particularly efficacious in chronic articular rheumatism, even where there is an anæmic, scrofulous, or syphilitic taint. The so-called nodosity of the joints has been successfully treated with iodine.

Arsenic is the great rival of corrosive sublimate, iodine, and muriate of ammonia in chronic rheumatism of the larger joints. Occasionally it produces marked amelioration, but it often fails, and is said to be useless in the most inveterate cases. It generally aggravates at first.

Phosphorus is a more reliable remedy in arthritis deformans, and phosphate of ammonia forms more soluble salts with uric acid than any preparation of soda or lime. Uric acid and the urates disappear rapidly from the urine made after its use, and pains and swellings of the joints are relieved as rapidly as from any preparation of soda or potash. It is fully equal to the other alkalies, and preferable to most of them in delicate and feeble subjects. It maintains a highly alkaline condition of the blood, has a distinctly alkaline reaction itself, and renders the urine alkaline.

Dr. Andrew H. Smith will read the next paper before the Section on "The Treatment of Dropsy with Apocynum cannabinum;" and Dr. Amidon will open the discussion on the local and dietetic treatment of chronic rheumatism.

SECTION IN OBSTETRICS.

Stated Meeting, December 23, 1885.

ALEXANDER S. HUNTER, M.D., CHAIRMAN.

DR. EGBERT H. GRANDIN read a paper, entitled

AN OBSCURE CASE OF ABDOMINAL GESTATION, WITH REMARKS BEARING ON TIMELY DIAGNOSIS AND TREATMENT.

Abdominal gestation is a rarity when compared with other abnormalities of pregnancy; the diagnosis is eminently difficult, and therefore it is why, as a rule, those who are unfortunate enough to meet with this condition fall into error, with the result of death of the fœtus, and not infrequently, also, of the mother. A study of the reported cases shows us that pelvic cellulitis, pelvic peritonitis, ovarian cyst, normal pregnancy, pregnancy in the retroflexed uterus, these and other conditions may be diagnosticated instead of abdominal gestation. The reason for this tendency to error lies in the fact that correct diagnosis is only possible through differentiation of the uterus from the abdominal gestation sac. Such differentiation is only, in the majority of cases, possible through resort to the uterine sound, and this instrument is contraindicated in the presence of marked classical and physical signs of uterine pregnancy, if the bimanual examination fails to differentiate certainly the uterus separate from the gestation sac.

In abdominal pregnancy, ordinarily, the history and physical examination suggest uterine gestation, except that there are present, in addition to the classical, rational, and physical signs, the further symptoms of intermittent attacks of pain, irregular discharges, and, perhaps, the passage of what might suggest a decidual membrane. This additional history, according to all our text-books, points strongly to ectopic gestation, and yet this history is very fallible. The irregular attacks of pain, particularly if accompanied by hemorrhage, will preferably suggest impending labor, or abortion, or uterine pregnancy complicated by placenta prævia, rather than the rarer condition—ectopic gestation. The decidua, if seen, and it rarely is, would be of only presumptive value in diagnosis, because both intra- and extra-uterine pregnancy may go on together to term, and therefore a decidua, and even a fœtus, may be passed without invalidating the presence of an abdominal gestation. Of course, if the physician waits and watches, he may disprove impending labor and abortion, but the reader of the paper contended that the physician need not and ought not to wait (indeed, in the interest of both the mother and the child, will often feel he has no right to wait), because there are always absent in advanced (beyond the fourth month) abdominal gestation signs which necessarily can only accompany uterine gestation. These signs are: the uterine souffle, the intermittent rhythmical contractions.

The first of these signs is only of negative value, because it is inconstant. If heard, it points to uterine gestation; if not heard, this is no certain proof that uterine gestation does not exist. The second of these signs is, in the reader's opinion, positive, and yet it is referred to by only one authority (Lusk), and he very briefly, as of value in differential diagnosis. These contractions are, in the hands of a careful observer, diagnostic of uterine pregnancy, and are present whether the fœtus be dead or alive. In case of abdominal gestation they must be absent, because the sac, if it contain any muscular fibre, does not contain sufficient to simulate uterine contraction. This sign, therefore, will always make the distinction between uterine and abdominal gestation.

Dr. Grandin then related an obscure case of abdominal gestation, which he had seen in consultation with Dr. W. J. Burnett, of Long Island City, and in which every means of physical examination failed to make the diagnosis until the sound established the vacuity of the uterus. In this case he did not think of the value of intermittent uterine contractions, else, he felt sure, he could have made the diagnosis without the sound.

This case brought prominently forward the question of treatment applicable to abdominal gestation. The conclusions reached were: If the child were viable, and at term, do laparotomy, which operation gave the child a chance, and did not materially alter the prognosis for the mother, always provided that, at the operation, the placenta were not interfered with. After the death of fœtus, the rule should be to wait until unfavorable symptoms supervened, when, unless the fœtus were small and *distinctly* presenting at some portion of the vagina, laparotomy should be resorted to. This position is in accord with the opinion of all authorities, and based on statistical data. The mortality percentage from opening through vagina is sixty per cent.; from leaving the case to nature's eliminative efforts is 52.65 per cent.; from laparotomy after death of fœtus varies from 15.+ to 38.+ per cent. Even in face of peritonitis, septicæmia, and deep exhaustion, laparotomy has been performed and life saved. Incision by the vagina resembles nature's crude efforts at elimination, and is, therefore, almost always followed by death resulting from the long-continued suppuration the patient is necessarily subjected to. Particularly are these remarks applicable to cases where the putrid fœtus lies high in the abdominal cavity, and therefore cannot be reached through any incision *per vaginam*. Through laparotomy, on the other hand, the putrid fœtus may be at once removed, and the source of suppuration and sepsis is thus taken away from the patient. The shock resulting from laparotomy is not, by any means, so great as that to which the patient is subjected by the prolonged suppurative process necessitated by vaginal incision, the chief reason being that the peritoneum, in the cases under consideration, has been subjected to insult for months, and is, therefore, less sensitive to the surgeon's knife than if it were a "new peritoneum." The reader therefore contended that laparotomy should ever be the operation of choice, especially to-day, when operators were more skilled, the value of strict cleanliness better appreciated, and when the technique of this operation had well-nigh reached perfection.

Dr. Barnim Scharlau read from the hospital notes of the case as recorded in the Mount Sinai Hospital, in which it appeared that the patient entered on August 24, 1885. For the past six weeks she had emaciated rapidly, had had fever, sweating, and after admission the temperature rose from 102.4° to above 104° F. Dr. Scharlau then gave the physical signs present when he examined the patient, the abdomen being distended by a large tumor which extended in the median line as high as the umbilicus, and which had the general form of a fœtus. The uterus was drawn up and pushed to one side; the sound entered to the depth of two and a half inches. The rectum was pushed to the right side of the pelvis; fluctuation was felt through the vaginal walls. [illegible] into the fluctuating mass in the vagina, and pus of a disagreeable odor was withdrawn. August 28th an operation was performed, the patient being under the influence of ether. It was not his intention in doing the operation adopted to confine himself to making an incision into the vagina, leaving the entire subsequent care of the case to nature. The first indication, he thought, was to evacuate the pus; and in making an opening into the vaginal wall for this purpose he thought that, if it were then possible by dilating the opening to reach the fœtal remains, they could also be removed. But after the escape of forty ounces of pus, a flexible sound was introduced to discover, if possible, a communication between the abscess and the amniotic sac, but no such communication could be demonstrated, and nothing could be felt with the finger excepting a soft mass which appeared to be a coil of intestine. Dr. Fluhrer was also unable to feel the fœtus. The patient's condition before the operation was very low. She did not stand the ether well, and there was danger, by further attempts to reach the fœtus, of penetrating the intestine; consequently, nothing more was done than to wash out the cavity, introduce a very large drainage-tube, and put the patient to bed. She did not fully recover from the shock of the operation, and died two days afterward. It was Dr. Scharlau's opinion that if laparotomy had been performed the patient would have died under the knife. At any rate, her condition was such as to lead him to select the more careful procedure.

Dr. P. F. Mundé said that when, during his absence from the city, he was informed of a case of abdominal pregnancy entering his wards in the Mount Sinai Hospital, and he was unable to return to take charge of it, he envied Dr. Scharlau, under whose care the patient then came, his opportunity; but since he had learned what proved to be apparently the inevitable result of the case, he had changed his mind. The difficulty of making a diagnosis in abdominal pregnancy was illustrated in a case seen by Scanzoni a number of years ago. After the patient had visited him he told Dr. Mundé that he had seen a case in which he could not say whether there was abdominal pregnancy, uterine pregnancy, or pregnancy at all. Afterward he made up his mind that it was a case of pregnancy. The patient died, and on the post-mortem table it was found that there was abdominal pregnancy. The case then appeared so plain that it seemed astonishing that a man of Scanzoni's experience should not have readily made the diagnosis, and saved the patient's life by laparotomy. Regarding the treatment in the case related to-night, personally he knew nothing about it, but from what he had heard he must agree with Dr. Scharlau that the patient's condition was so low that it would not have been proper to do anything else than to evacuate pus, which was causing sepsis, by making an opening at the most accessible point, namely, in the vagina. He was speaking, however, of this particular case, and not of cases generally. Here the indication to evacuate the pus could not have been so well met by laparotomy. Drainage by that operation would not have been so good, and shock would have been greater. Probably the patient would have succumbed sooner to shock, although only slightly greater, had abdominal section been performed.

But he agreed also with Dr. Grandin when he said that laparotomy in general was the proper treatment for these cases. If he could feel a fluctuating mass, containing fœtal bones, in Douglas' cul-de-sac, he should probably make an opening there; but usually the fœtal parts were situated higher up, and here laparotomy should be performed, the fœtal remains be removed, and drainage effected. Dr. Mundé had seen Dr. Thomas perform laparotomy in these cases several times, and he had been surprised at the ease with which he carried out the procedure, and by introducing a drainage-tube and irrigating the cavity the patient recovered without any difficulty.

Concerning diagnosis, he thought the point regard-

ing contractions of the uterus made by Dr. Grandin a good one. But practically Dr. Mundé could say little; he had seen only one case of abdominal pregnancy, and in that instance only on one occasion. After diagnosis he did not think operative interference should be undertaken until term, and then the question would arise as to the possibility of saving the life of the child. There were a number of cases in which the fœtus had been extracted after laparotomy, the placenta being left to come away after its own manner. He thought this a perfectly justifiable procedure if the child were alive and viable. If the child were known to be dead, he should think the lapse of a short time before resorting to an operative procedure would matter little, but he did not believe we should wait for septic symptoms to appear, or for the bones to work their way into the external world through the rectum or other passage. He thought it would be perfectly justifiable before this period had arrived to make an exploratory incision and remove the foreign substance.

Dr. W. T. Lusk said we owed a debt of gratitude to anyone who would give so distinct an account of a well-observed clinical case as had been presented this evening; we were especially under obligation to Dr. Grandin for bringing out so clearly the diagnostic points, which, under any circumstances, are none too definite in these cases. Last May Dr. Barker, Dr. Thomas, and Dr. Lusk saw a patient who came from the West; she had gone to the full term of gestation, and had been carrying a child in the abdominal cavity six months after its death. She had stopped to see a gynecologist out West, well known to all of us, who examined her carefully and said that she was suffering from a fibroid of the uterus. He cautioned her against falling into the hands of surgeons in this city, telling her to enjoy herself, spend her time quietly, and to keep away from the surgeons. The case simply showed how eminent men will make mistakes in diagnosis in abdominal pregnancy. It was not necessary at that time to operate, but the patient will probably soon return for an operation.

While all agreed that it was desirable to perform laparotomy, to save, if possible, the life of the child, it was well to bear in mind the results of such operations. There were thirty-one such cases on record, and in only two did the mother recover. Therefore, the method of operating must be improved before we could entertain hope of good results. All of the twenty-nine patients died of hemorrhage or of profuse suppuration following it.

Dr. Lusk then related the following case, which in many respects was parallel to the one related by Dr. Grandin: The woman was a Hungarian, thirty-two years of age, who entered Bellevue Hospital on May 25, 1885. She was the mother of three children, the youngest of whom was three years old. At the birth of this child she had no medical attendance. It seemed that a severe laceration occurred, the exact nature of which was unknown, and intense inflammation followed. Finally, she was taken to Mount Sinai Hospital, and while there an operation was performed for laceration of the cervix. She was benefited by rest and the operation, and went out of the hospital, but soon intense pelvic pains developed. In spite of this, however, for a year and a half she did her ordinary work. The pain then became so severe that she called a physician, who took charge of her for four or five days. For six months she was unable to work. She entered Bellevue Hospital May 25, 1885, having been seized with profuse hemorrhage. The discharge of blood had been intermittent, occurring sometimes at intervals of two weeks, sometimes three weeks; but lately the intervals were much shorter, and during the last profuse hemorrhage she was seized with violent pains, and went into partial collapse. Dr. Lusk saw her the next day, when he found a large flaccid tumor, situated behind the uterus, and pressing the organ upward and forward; its outlines could be distinctly mapped out. Dr. Lusk thought it was a case of recent hæmatocele. At the end of a week he examined the patient again, and found that the tumor had increased in size, and, instead of occupying the median line, it was to the left side. He then suspected extra-uterine pregnancy, but on passing a hypodermic needle into the sac he withdrew it full of blood. This seemed to confirm his first diagnosis of hæmatocele. The patient remained in the hospital with symptoms of pelvic peritonitis and cellulitis, and symptoms due to pressure of the tumor, until the 15th of June, when he examined her again, and found that the tumor had increased very rapidly, and now occupied for the most part the left side. Tension was very great, the uterus reached nearly as high as the umbilicus; there was distinct pulsation of the vaginal parts, which left very little doubt as to the nature of the case. Still he felt puzzled from the fact that before, on introducing the syringe, fluid blood was withdrawn. He was, therefore, tempted to do that which he would not recommend any one else to do, namely, to introduce the needle again. This time he got clear fluid, and it was decided to be fluid from the amniotic sac. The child was no doubt living; the tumor was growing; the vaginal arteries were pulsating distinctly. The faradic current was applied that night, twice the next day, and on the morning of the third day, the 19th of June. On the afternoon of this day acute inflammation developed, thought to be probably due to introduction of septic matter on the needle. This continued for several days, but on the 2d of July the temperature suddenly fell to 95.5° F. in the axilla, and to 97.5° F. in the rectum, and the patient said she felt a great deal better. Diarrhœa set in, the pulse became very rapid and very compressible. For two or three days she continued to feel better, and then had a violent chill; the temperature rose to 103° F.; on the 9th of July it was 104° F., and it continued high on the 10th. The next day if fell somewhat, and the temperature chart presented a moderate curve until the 15th, but the pulse was very rapid and compressible. These observations were made by the house physician, Dr. R. Sayre, as Dr. Lusk, soon after making use of the faradic current, went to Europe. On the 15th of July the nurse noticed a tumor projecting from the rectal wall, and Dr. Sayre on examination found the posterior vaginal wall torn up to its junction with the uterus, and through this opening his finger came in contact with a fœtal head. He extracted the fœtus, which measured about eighteen inches in length, and was attached to the cord, which measured about eight inches. He then introduced his hand into the sac, which had thick walls, and removed the placenta piecemeal. All portions of the sac except that to which the placenta was attached were perfectly smooth. When he finished the pulse was 144, the respiration about sixty. It was thought the patient was about to die, and they did not wait to wash out the sac, but put her to bed, gave digitalis, and had the nurse administer whiskey, a few drops at a time as the patient could be made to take it. The patient having rallied somewhat by evening, the sac was then washed out. Death seemed to be inevitable, but by judicious treatment and constant care the patient was cured, and on Dr. Lusk's return to his service in September, she was walking about the wards. She was discharged the 1st of October, entirely well.

The case was interesting to the speaker because there was, as there commonly is in cases of extra-uterine pregnancy, a long antecedent history of pelvic inflammation; then there developed hæmatocele, for there must have been hemorrhage into the peritoneal sac, as was demonstrated by the withdrawal of blood by the syringe, and this gave rise to difficulty in diagnosis. Use of the electric current caused death of the fœtus, and unfortunately at this time a septic process was set up by the introduction of poisonous matter with the exploratory needle. The patient owed her life largely to the judgment exercised by Dr. Sayre in the management of the case; instead of observing a fixed rule in washing out

the cavity of the sac with an antiseptic fluid, as theoretical considerations might seem to indicate as the proper course, he made the injections only at such times as the patient seemed best able to withstand the disturbance. When she was extremely feeble the injections were omitted.

Dr. E. L. Partridge said he had nothing to contribute in the way of clinical observation. With regard to the diagnostic value of intermittent uterine contractions, he thought it a very good point to be made; perhaps it was the most important differential sign between uterine and abdominal pregnancy after four and a half months had passed. But even with this and all other signs he thought we were in danger of making a mistake in diagnosis, and for this reason he would take occasion to emphasize the importance of more careful study of ordinary cases of pregnancy. The more familiar we were with the signs of natural pregnancy the more likely would we be to detect abdominal pregnancy should a case occur in our practice. Each case had to be considered upon its own merits, and he thought the value of uterine contraction in diagnosticating uterine pregnancy, as distinguished from extra-uterine pregnancy, would be like that of *ballottement* as a sign of ordinary pregnancy; when it could be clearly made out the diagnosis would be positive, but the difficulty would rest in assuring ourselves that this sign existed.

Dr. H. J. Garrigues corrected the author, who said he, Dr. Garrigues, in going over the literature of the subject for four years had found four hundred cases of extra-uterine pregnancy; he should have said two hundred cases. The point he desired to make, however, was sustained, namely, that extra-uterine pregnancy was far from being as rare as the text-books would lead us to believe. He thought the author was correct in laying stress upon the presence or absence of uterine contractions in the differential diagnosis between uterine and abdominal pregnancy. But he was unable to speak from experience, inasmuch as he had seen only one case of advanced abdominal pregnancy, and that was many years ago, when he less appreciated it than he would now, and the patient was in another man's care. He would call attention to another symptom, probably little known, but which was pointed out by Dr. Howard, of Baltimore. Dr. Howard argued that if the fœtal heart-sound could be heard near the abdominal wall, and the uterine souffle could not be heard, it was a sign of abdominal pregnancy. We often had the opposite condition, presence of the uterine souffle, and absence, so far as could be heard, of the fetal heart-sound; but presence of the souffle did not necessarily point to uterine pregnancy, but this sign would be present only after pregnancy was well advanced.

With regard to treatment, he differed somewhat from the teachings of others, especially those of Dr. Thomas, both in the earlier and later periods. He thought that in the early period we should certainly destroy the life of the fœtus by electricity, which is an entirely safe and reliable method. With regard to how far the period for adopting this treatment should be extended, he advocated its use at any time. In fact, it had been employed at the end of the sixth month, in a case reported in a Berlin journal, and the patient afterward menstruated regularly, gained in flesh, and was in good health. The tumor, after destruction of life by faradization, became nodular, increased in hardness, and greatly diminished in size.

Dr. Garrigues did not believe in the employment of laparotomy. He thought the statistics given by Dr. Lusk were very convincing; there were thirty-one cases, twenty-nine of which ended fatally. If we compared with these statistics those of secondary laparotomy, the results in the latter were very good, considerably more than half recovering. He would not agree with Dr. Mundé in advising that laparotomy be performed after death of the fœtus when the woman was in good health, for there were a number of cases on record in which the fœtal remains became mummified, and the woman retained her health. Should she become sick, however, and fever set in, he should do laparotomy.

Dr. Malcolm McLane directed attention to the importance of making an examination under anæsthesia in doubtful cases.

Dr. H. J. Boldt referred to a case of abdominal pregnancy, which he published in the *American Journal of Obstetrics* in 1880, and said that the history of the case differed from that of the case related by Dr. Grandin, in that there had not been pelvic inflammation nor irregular discharges.

Dr. Grandin, in closing the discussion, said that he had not intended to criticise the treatment adopted by Dr. Scharlau in this particular case; his remarks were intended only to be general. Under the circumstances he probably should have adopted the procedure carried out by Dr. Scharlau. With regard to the value of examination under anæsthesia, he was unable in this instance to make a correct diagnosis until the patient had been anæsthetized.

The Section then adjourned.

Correspondence.

OUR LONDON LETTER

[redacted]

An unfailing object of interest, with the commencement of a new year, is the appearance of the annual volume known as "The Medical Directory." This is not an official publication, although it is supposed to be such by many uninitiated persons. It is, though, far more trustworthy than the official "Medical Register," being compiled from annual returns from members of the profession, most of whom comply with the request to return the annual form sent for corrections. From this reason it is also a very interesting work, and compares very favorably with the arid columns of the "Medical Register." Many curious and interesting facts may be gleaned by glancing through its pages. We see, for instance, that among the older hospital surgeons all those who have the F.R.C.S. Eng., put (Hon.) after it, showing that it has not been acquired by examination. *So far as examinations go*, therefore, their position at the College is not better than that of simple members. It might fairly be claimed that it is not so good as that of a modern member, considering that thirty years ago the only test of knowledge applied to candidates for the M.R.C.S. consisted of an hour's *viva voce* examination by members of the Council, thus differing widely from the varied ordeal through which present-day students have to pass. Examinations are not, of course, everything, and it is only the rising generation which thinks so. Still, the fact recorded above is not without interest taken into consideration in connection with the controversy still raging as to the rights of members. The honorary fellows include among others such honored names as James Paget, Richard Quain, Samuel Lane, Thomas Blizard Curling, Charles Hawkins, Prescott Hewett, George Viner Ellis, John Simon, William Bowman, Spencer Wells, Wharton Jones, and George Murray Humphry. The above list might easily be extended. Among the above are several ex-presidents of the College, and four baronets.

The varied lengths of the entries in the "Directory" is not without interest. Many medical men apparently try and make the most of themselves, their qualifications, and published writings. Others go on the opposite tack. Among the former must be placed the gentleman who styles himself M.D. (Logic) on the strength of having

passed his examination for the M.D. at the London University in logic alone, which forms a very minor part of the examination. The number of senior demonstrators of anatomy at University College is, too, something bewildering if the "Directory" is to be taken as evidence on this point. Under the latter category must be placed no less a person than Professor Ringer, who, with a commendable zeal for brevity, does not insert the names of any of his published works. Here also must, I presume, be ranged a London surgeon who, a few years ago, inserted M.B. Camb. after his name, but has apparently thought better of this and now omits it.

A reference to the "Directory" will also show that the ophthalmic surgeon at one of our largest London hospitals was educated in the first instance for the veterinary profession and qualified as a veterinary surgeon; that one of our best-known ovariotomists began life as a naval surgeon, and that a well-known obstetric physician began his career as a surgeon in the Indian army. The paucity of graduates of the University of London among London practitioners is very apparent. Many graduates of that university in arts and science have apparently been forced to go to other universities to qualify in medicine.

Some time back the Medical Temperance Association (consisting of medical men who are themselves abstainers) offered a prize of one hundred guineas to the best essay on the subject written by a medical student. The award has just been made. The increasing number of abstainers among medical men and medical students is shown by the large number of competitors, and by the fact that three are named as worthy of special mention, besides the actual prize-winner.

In some recent visits to the out-patient clinic of the Hospital for Diseases of the Throat I have had the opportunity of observing several interesting cases. One was a rare case of hemorrhagic laryngitis complicated with facial erysipelas, and the existence of an abscess in one of the cervical glands. Strange to say, the general health of the patient did not seem much affected. Treatment was at first directed to the erysipelas. At the second visit this had disappeared. I also saw a case of malignant disease which strongly reminded me of the published medical account of General Grant's case. It seemed to have begun much in the same way, but had extended so far on his first application to the hospital, that it seemed as if the patient could not long survive. Another interesting case was one of anchylosis of the right arytenoid cartilage. It appeared to have existed for some time, the patient having come under treatment for an attack of acute laryngitis supervening on a chronic affection. There was no history of syphilis or tubercle, but the patient was in bad health, and it was feared that the cartilages were affected. In one afternoon I saw five cases of stricture of the œsophagus. Two of these were evidently malignant and in an advanced stage; one was apparently either fibrous or syphilitic, in a young man, for whom large doses of iodide were ordered; one, in a man about forty, seemed to be pouched, and regurgitation of food was tolerably constant; the other, in a young woman, was apparently spasmodic.

PROFESSOR HAMILTON'S PAPER ON THE "ART OF PRIMARY UNION," AND DR. T. R. VARICK'S HOT-WATER APPLICATION.

To the Editor of the Medical Record.

SIR: Anything from the pen of Professor Frank H. Hamilton is interesting and of benefit to the medical profession, owing to the writer's long and extensive experience in the field of operative surgery.

The aphorism that "There is nothing new under the sun," is well proven by Professor Hamilton's historic account of "union by adhesion." That the success of operators a hundred years ago should equal, if not excel, the success of modern operators is *mirabile dictu*. Can it be that surgery is so non-progressive as this? Indeed, until the past decade or so there was really a retrogression. To-day we have only recovered the ground lost and returned to the methods in vogue during the days of Alanson and his contemporaries. Where can any modern operator show results equal to those obtained by Alanson in 1779—thirty-five successive cases of capital amputation safely piloted to recovery?

Professor Hamilton's disposal of Listerism is at once effective and conclusive. The suspicion of jugglery and humbuggery attached to the Lister method works to its disadvantage. Science deals only with truth and fact—not with pretence and fiction.

The blind devotion and infatuation with which some of the followers of Lister advocate and practise his tenets is akin to the superstition of certain African tribes who believe in fetich.

To some, otherwise sane and rational medical scientists, Listerism is a veritable *ignis fatuus*.

To a specious and questionable theory they attribute a success that is due simply to an improved mode of operation and treatment. A strict attention to detail in operation and treatment, perfect cleanliness, and proper drainage is the true reason for Lister's success, and not his germicides and gauze.

To that famed and most odoriferous drug, that remorseless exterminator of germs—carbolic acid—supernatural powers are attributed.

Professor Hamilton, in commenting upon the treatment of large incised wounds, refers to a paper read before the New York County Medical Association in February, 1885, by Dr. Theodore R. Varick, Surgeon to St. Francis' Hospital, Jersey City (not Newark, as stated in Professor H.'s paper).

The article in question was entitled, "The Protective Treatment of Open Wounds," and advocated the application of hot water, or water a little below the boiling point, to the raw surfaces of wounds immediately after the larger vessels had been tied, the application to be kept up until all oozing had ceased and the parts thoroughly glazed.

The Professor goes on to state that Dr. Varick attributes his remarkable success (a recovery of thirty-seven cases out of thirty-nine capital amputations) to the power of hot water to close hermetically the capillaries, and thus prevent the admission of germs. While Professor Hamilton endorses Dr. Varick's practice as valuable, and one he had often adopted himself, he does not accept his theory, on the ground that the most of the cases reported by Dr. Varick were of the class known as "railroad injuries," and as a consequence there must have been extensive exposure of the vessels by laceration, thus affording, for some time previous to the operation, an unimpeded opportunity for the ingress of atmospheric germs.

If the Professor had read over more carefully Dr. Varick's paper he would not have made the mistake of unintentionally misrepresenting him.

Dr. Varick, in describing the dangers of immediate absorption of atmospheric germs after railroad injuries, where there has been laceration of the soft tissues, says: "As before suggested, the open stomata of the vessels would seem to offer special opportunities for the introduction of atmospheric germs, and the imbibition of any extraneous poison, gaseous or fluid. Such would be the case were it not that the flow outward—which occurs at the time of the infliction of the wound and continues for a greater or less period thereafter—of the fluids washes away any foreign substance which may lodge on the abraded surface.

"From arteries and arterioles there is an accelerated current, from the veins and venules a reversed current, and from the lymph spaces an outward flow—all exerting a conservative influence and temporary protective power; so long as these exudations occur the patient is safe from contamination from without."

As has already been stated, Professor Hamilton's objection to Dr. Varick's theory is based on an assumed exposure to infection of a lacerated wound from the time of its inception to the time of treatment. The above quotation from Dr. Varick's paper answers this objection, and offers a very plausible theory for the protection of the patient from atmospheric germs (if such things really exist) during the *ad interim* period. Provided the patient is not in *articulo mortis*, there is an invariable oozing sufficient to prevent the ingress of septic matter.

This theory of Dr. Varick is not only tenable but clearly proven—supposing, of course, that there is no doubt as to the existence of atmospheric germs and their capability of absorption by raw flesh surfaces—by the absolute immunity from all septic complications of the thirty-nine cases reported by him.

Professor Hamilton, commenting further upon the use of hot water in surgical operations, says: "Dr. Varick recommends that the water have a temperature 'slightly below the boiling-point.' This might do if one were to apply it by means of a sponge, and then only for an instant, as I have often done to close a bleeding arteriole, but if employed continuously or by irrigation through the nozzle of a tube it ought not to exceed in temperature 112° or 115° Fahr., or the temperature which may be easily borne by the naked hand."

The chief purpose for which Dr. Varick advocates the hot-water application is to coagulate the albuminous flow from the stump or wound and constringe the bleeding orifices of arterioles and venules. Water at a temperature of 112° to 115° Fahr. would utterly fail to secure either coagulation of albumin or constringement of arterioles and venules; indeed, as to the latter, it would rather favor hemorrhage than restrain it.

To coagulate albumin hot water must have a temperature at least of 140° Fahr. Another very important property of hot water is to promote reaction, when applied to muscular and nervous tissue stilled to a passive and lethargic condition by the influence of the anæsthetic. To secure this reaction the water must be *hot*, not *warm*.

Dr. Varick thus describes the effect of hot water upon the albuminous flow from an incised wound: "In a coagulated state it (albumin) covers the face of the stump or surface of the wound, forming a perfectly fitting impenetrable shield, plugging up every capillary stoma; where heat is the agent employed, constringes every arteriole and venule, and if applied before the outward flow from the divided vessels has ceased, makes the patient absolutely safe from any septic infection from without whatever." This, the doctor says, is a sweeping assertion, but it is based on a long and varied experience.

For the past fifteen years it has been my good fortune and privilege to be associated with Dr. Varick, as a surgeon to St. Francis' Hospital, Jersey City.

Seeing the wonderful success that attended his operations I was led to adopt his method. Previous to the use of hot water at operations, the ordinary methods of the day had been employed. Listerism had been given a fair trial—the attention to detail so earnestly enjoined by its originator had been faithfully carried out, but the results were not such as would warrant a continuance of its use. Possibly it may have been due to some fault in my use of "the method"—perhaps the carbolic acid solutions may have been not just of the proper strength—or I may have inadvertently forgotten to properly carbolize some of the paraphernalia pertaining to the "system." However, I followed directions as closely as possible—carbolized everything and everybody. If an atmospheric germ was able to survive in the operating-room he must have been a very sthenic germ, for the carbolic fumes nearly killed the operator and his assistants.

Of a total of forty four amputations I performed before using the Varick method, sixteen died—five of these cases were treated *à la* Lister, with two deaths. Since I have used the Varick method I have had twenty-nine amputations, with six deaths. Of these six deaths not one could be attributed to a septic complication. One half of the previous sixteen deaths were due to blood-poisoning, the two deaths under the Lister system being unmistakably due to that disease.

A thorough system of drainage in the after-treatment of incised wounds, with perfect cleanliness, is a *sine qua non* to success. This, with the use of hot water at the time of operation, and a painstaking and conscientious attention to detail, as recommended by Velpeau, Lawson Tait, Hamilton, and others, will secure results, in my opinion, far exceeding the success claimed for Listerism or any other antiseptic process.

JOHN D. McGILL, M.D.,
Surgeon to St. Francis' Hospital, Jersey City, N. J.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 10, 1886, to January 16, 1886.

SWIFT, EBENEZER, Lieutenant Colonel, U.S.A. (retired). Died near Hamilton, Bermuda, December 24, 1885.

New Instruments.

A NEW PATTERN OF URETHRAL SOUND.

ONE who proposes to the profession a new instrument must needs apologize, hence I offer the proposition and the apology together.

I invite the attention of the profession to a new pattern of urethral sound. The straight shaft is six and one-half inches in length—the average length of the spongy urethra; the curved and conical part three-fourths of an inch in length—the average length of the membranous urethra; the tip is three-fourths the size of the shaft. Hence, when this instrument is passed

into the average urethra its full length, the commencement of the straight full-sized shaft is at the triangular ligament, and the tip is at the apex of the prostate. The prostatic urethra is not invaded at all. Its advantages over the full-curved sound are several. By its use we get all the benefit that can be had from *any* sound, with none of the mischiefs which are liable to follow the invasion of the prostatic urethra and the bladder; it being conceded that in more than nineteen-twentieths of the cases of urethral disease, for which the frequent use of steel sounds is indicated, the disease is in front of the deep perineal fascia.

1. *It does not cause prostato-cystitis*, which frequently follows passing instruments into the bladder, and which is especially to be deprecated when the bladder is already affected with a mild, chronic hyperæmia or inflammation, which is common in such cases.

2. *It does not induce epididymitis* which only follows instrumentation which mechanically irritates the floor of the prostatic urethra.

3. *It does not induce urethral fever.* That rarely, *if ever*, follows instrumentation or operation below the deep perineal fascia, though further observations on that point are admitted to be desirable.

4. *It causes less pain, and no unnecessary pain.* (See Dr. Weiss' article on the above subject in No. 25 of THE RECORD, for December, 1884.)

Its advantage over a straight instrument is: *Facility of introduction* when the disease is *at* the bulb of the urethra. I have always used a straight sound for the penile urethra, and prefer it, and only pass it through the diseased part; but for disease *at* the bulb, a conical sound *must* pass through the triangular ligament. Here the sound proposed passes as readily as a full curved one, and a straight instrument is here with difficulty passed through both stricture and ligament, even by an expert. Further, the curved part is so short, that, in the penile urethra, where a straight instrument is preferred, this sound answers the purpose about as well, and very much better than one with the full curve. I have a set of eight instruments—every third number of the French scale, from fifteen to thirty-six, inclusive, which were made for me by Tiemann & Co. It is not claimed that the above presents any original points of doctrine, only that the instrument proposed better fulfils well-known indications.

THE LACKAWANNA COUNTY MEDICAL SOCIETY.—Dr. M. J. Williams, of Scranton, Pa., writes: "In looking over my RECORD of the 26th ult. I saw a statement that, 'at a meeting of the Lackawanna County Medical Society, held December 8th, a telegram was received from Dr. J. V. Shoemaker, of Philadelphia, asking the society to rescind their resolution of last month condemning the action of the American Medical Association's new committee in excluding eminent physicians from the Congress. A motion to reconsider the resolution of last month was offered, and, after an animated discussion, was defeated.' How much truth there is in the above statement you will readily see from the following facts, gleaned from the transactions of the Lackawanna County Society for November and December, it being necessary to give both months in order that the subject may be better understood. At a very poorly attended meeting held November 10th, a resolution, condemning the action of the American Medical Association's new committee, was offered and championed by a comparatively new member; in fact, it being his first attendance as a regular member of the society, which received six votes out of a society numbering forty-five members, which truly cannot be considered a very strong expression of the society. Remember, those six included the maker of the resolution, and some that rarely attend the meetings of the society, and only in this case for the express purpose of passing this resolution. Having succeeded in carrying their motion, in order to make the matter more emphatic a second motion was made, to appoint a committee of three to draw up a set of resolutions condemning the action of the new committee of the American Medical Association, which was carried by the same vote as the first motion. But, alas, this proved to be the straw that broke the camel's back, as we learned from the subsequent meeting, held December 8, 1885. The meeting of December 8th being our regular monthly, as well as annual meeting for the election of officers for the ensuing year, was largely attended, there being twenty-nine members present. This proved to be the largest, and most representative meeting ever held of the Lackawanna County Medical Society. Not only was Scranton well represented, but there were present members from Carbondale, Oliphant, Fleetville, and other towns, making it a truly representative meeting. At this meeting, when the condemnatory resolutions were presented, they were defeated by a vote of nineteen to ten; one of the ten not being a member, the vote really stands nineteen to nine, leaving no doubt as to the defeat of the resolutions. A motion was then made to reconsider the action of November, which was carried by the same vote that defeated the resolution. The President being asked to cast his vote, did so with the majority, making twenty votes for reconsideration. In relation to the telegram sent by Dr. J. V. Shoemaker, of Philadelphia, asking the society to rescind their action of November, I will say, the society never received any such telegram. I believe Dr. Throop received a message from Dr. Shoemaker, but as that was private it certainly did not belong to the society. In order that you may see some of the animosity that exists toward Dr. Shoemaker by one of the party that supported the November resolutions, allow me to give the expression in his own language, verbatim, 'I am glad to get a chance to sit on that Shoemaker.' I have submitted this communication to both the president and secretary of the Lackawanna County Medical Society, for their inspection, verification, and approbation, which they fully endorse by adding their official signature. In conclusion, allow me to say that the great majority of the members of the Lackawanna County Medical Society feel sorry that matters exist as they do in relation to the International Congress, but we also wish it understood that we feel loyal to the American Medical Association. Trusting you will pardon me for trespassing so much on your valuable space, expecting to be treated fairly, asking no more, nor expecting any less, I remain, very respectfully,

"M. J. WILLIAMS, M.D.

"B. H. THROOP, *Pres. L. M. Soc.*
"W. A. PAINE, *Sec'y Lack. Co. Med. Society.*"

ANOTHER NEW JOURNAL.—The *Chirurgicheski Vestnik*, "Surgical Courier," is the title of a new monthly journal which is announced to appear early in the present year in St. Petersburg. The editor is Mr. N. A. Velyaminoff.

TREATMENT OF SINGULTUS.—Pagenstecher reports a case of obstinate hiccough, which had resisted all the ordinary remedies, cured by an infusion of jaborandi leaves. The spasm ceased as soon as profuse sweating occurred.

THE MODE OF ACTION OF ANTIPYRIN.—Dr. Francesco Coppola, after excluding one by one all the causes which can effect a reduction of temperature in the animal organism, concludes that the antipyretic effect of this drug depends solely upon an increased dispersion of caloric, and not upon any central action.

AN INTERNATIONAL CONGRESS OF CRIMINAL ANTHROPOLOGY was held in Rome, in November, 1885. The members indulged in prolonged discussions upon the etiology, psychology, and pathological anatomy of crime. The sessions were presided over by Professors Lombroso and Terri.

DEATH IN A DENTIST'S CHAIR.—A Parisian dentist, M. Duchesne, recently had the misfortune to lose a patient to whom he had given an anæsthetic previous to the extraction of a tooth. The dentist, being neither a physician nor an *officer de santé*, was adjudged to have illegally administered the anæsthetic, and therefore to have been guilty of homicide. He escaped, however, with the payment of a fine of 3,600 francs. It would thus appear that homicide, as defined by the French courts, is a pretty cheap recreation after all

Original Articles.

CATARRHAL INFLAMMATION OF THE UPPER AIR-TRACT.[1]

BY SAMUEL SEXTON, M.D.,

It has not been long since inflammation of the mucous tract of the head was simply known as a "gathering" in the head. Of late this has given way to a term less expressive of the trouble, namely, a "cold in the head." Gradually, however, as catarrhal affections of the ear and nose have received greater attention, their importance is more generally recognized, and it now seems time that the entire pneumatic tract of the head should be considered as a whole, in order that the etiology, pathology, and treatment of this region, or any of its parts, may be intelligently considered. It will be profitable to those who have not already given the subject particular attention, to glance at the pneumatic area of the head, as shown in the accompanying diagrammatic view of this region.[2]

FIG. 1.—Diagram of Upper Respiratory Tract and its Accessories [illegible] S, M, I. superior, middle, and inferior turbinated bones; 5, 5, antrum of Highmore; 6, 6, [illegible]; 7, 7, sphenoidal sinuses; 8, 8, [illegible] sinuses; 9, 9, sphenoidal sinuses; 10, 10, frontal sinuses; 11, 11, infundibulum; 12, 12, Eustachian tubes; 13, 13, tympanum; 14, 14, mastoid cells; 15, 15, mastoid sinuses.

Greater knowledge of the boundaries and extent of the tract may, however, be obtained by studying the prepared bones of the face and head. The osseous forefront in man will thus be seen to consist of a framework not unlike the bony structure in birds, where extreme lightness is assured without undue loss of strength—a conformation well adapted to the physiological requirements of the special-sense nerve distribution to the ear and nose.

The more important cavities of the head concerned in catarrhal inflammation are: 1, the tympanum, mastoid antrum, and cellules; 2, the turbinated bone interspaces; 3, the frontal sinuses; 4, the ethmoidal cells; 5, the antrum of the superior maxillary bone; 6, the sphenoidal sinuses. The large sockets for the lodgement of the eyes, the oro-pharynx, the pharyngeal vault, and the nasal passages, are also a part of this region. The various cavities have connecting sinuses, and the entire system is everywhere lined by mucous membrane.

It is manifest, then, that no one part of the upper air-tract is liable to catarrhal inflammation altogether independently of the others. Before alluding to causation in a broader sense, however, a passing allusion may be made in this connection to several important local anomalies and affections which sometimes stand in a causative relation to catarrh. Thus, deviations of the nasal system occur often enough to attract attention to their possible influence in causing catarrhal inflammation; where this interferes with free circulation of air and the escape of secretions, it may be not only causative of catarrh, but may also increase its dangers. The relations of deviations of the nasal septum to a high palatal arch are notably frequent, and from a study of a large number of subjects of this defect in catarrhal patients, I cannot believe that it has any other significance than that it seems to pertain to individuals with marked ovoidal conformation of the face, who generally have high-arched palates along with the lengthened facial measurement. Diligent search for an explanation of the high arch, in connection with the development of the teeth, was made of the writer's collection of plaster casts of the jaws, several hundred in number; but it would seem that the teeth have no influence in narrowing the arch. The height of the palatal arch has not, so far as I can discover, any significance in respect to a hereditary catarrhal tendency, nor does it bear an unvarying relation to deviations of the nasal system.

Hypertrophy of the tonsils, turbinated bodies, and the mucous membrane of the pharynx (adynoid vegetations), are very common results of catarrhal inflammation, and when present are to be considered as exercising an influence on the mucous tract in the neighborhood as well as remotely through their nervous connections; but while they require attention at the hands of the otologist, the subject would, if followed out in detail, carry me too far.

My own experience, in observing catarrhal inflammation of the head and elsewhere, leads me to rather regard it as the local manifestation of systemic and climatic influences, than, as some authorities intimate, the result of a purely catarrhal diathesis to the local manifestations of which treatment is mainly to be directed. I can but think it a fallacy to consider even a strong predisposition, manifesting itself in the guise of heredity in persons seldom free of catarrh, as demonstrating the purely local nature of the trouble.

In defining catarrhal inflammation it is well to distinguish between the deterioration in mucous surfaces which evinces the natural retrogradation consequent on gradual but sure decay, and the conditions that hasten the process, and, therefore, call for medical treatment. But while natural retrogression is in a measure irremedial, yet it is much less active in the strong and healthy. Catarrhal inflammation manifests itself very differently in different cases; thus the healthy and strong withstand its influences, while the weak and susceptible yield readily. The predisponents and excitants of catarrh give coloring to its manifestations; thus, urban and rural environments, respectively, with the diversity in the habits or occupation of individuals, together with climatic differences, produce very different effects, and it will be well to review their peculiarities separately.

Urban peculiarities.—In cities mental strain from overwork, worry, and dissipations of every kind—in a word, civic wear and tear—gives rise to nervous exhaustion, and consequently to mental and physical disability.

To the above should be added the ceaseless noise and the exceedingly deleterious dust and offensive and noxious odors with which metropolitan air is generally laden.

[1] Read before the Practitioners' Society, June, 1885.

[2] Drawn by Dr. Lennox Browne at the suggestion [illegible]

Persons almost exclusively reared in cities are, moreover, deprived of the tone and vigor imparted by country life.

The mucous membrane of the air-passages in all persons is thus exposed to a variety of local excitants, but among clerks and operatives it is especially liable to become inflamed. Perhaps worse than all else is the pernicious system of overheating dwellings, hotels, schoolhouses, public resorts, factories, railway carriages, and sea-going vessels. Provision is thus made for the comfort of the ailing or indolent on the one hand, and the economical distribution of heat on the other, without due regard for the consequences on health. These unwholesome conditions are the outgrowth of luxurious civic life, the concentration of mercantile and manufacturing interests, the criminal neglect to keep streets and houses clean, and defective drainage. Thus while out-door air has its impurities at all seasons, it is scarcely possible during the winter to live in-doors without experiencing the ill-effects of overheated and impure air, the tendency of which is to deprive persons of the hardihood necessary to resist the unavoidable and natural vicissitudes of out-door life.

The liability to contract catarrhal affections from exposure of the feet, trunk, and head, in street-cars, to draughts of cold air in all seasons is very great.

Rural peculiarities.—Very different from the foregoing are the usual conditions of country life; here physical overwork is more likely to be met with as compared with mental, although worry and grief in various forms are not unknown. Among pioneers in new settlements homesickness often exists, the food-supply frequently is inadequate, and habitations damp, cold, and dark. The statement applies to laborers in public works, and often to men in the frontier military service. In older and improved country places, where extreme exposure is exceptional, catarrhal inflammation is not so severe, yet the causal influences and symptoms differ from those of the city. It may be said that the rural subject presents the sthenic type, with greater temperature disturbance, while in the city patient, if a subject of nervous exhaustion, it is more likely to assume an asthenic form.

The difference in the phenomena observed in what may, for comparison, be designated as two classes of catarrhal disease, serves perhaps to explain some apparent discrepancies in the conclusions arrived at by medical men, who have looked on the same disease from a different point of view, some regarding it as catarrhal inflammation, others as malarial fever.

But this is not so surprising, since catarrhal inflammation often exhibits symptoms commonly, though wrongly, ascribed to malaria; thus fever is often present, being ushered in with chills; there is a tendency to recurrence, malaise, depression of spirits, vertiginous symptoms, and the like. The subsequent debility and typhoidal symptoms, when present, are therefore liable to mislead the observer, especially if he be a believer in the production of typhoid fever from "malarial" influences. One should reflect here on the possibility of these symptoms being due to disturbance of the nervous system wholly.

Malaria has long been a convenient cloak for our ignorance in respect to the origin of disease. The writer recollects how the "bilious remittent" fever of the Southwest was attributed to this cause in his early experience; and an outbreak of so called "typho-malarial" among the soldiers of his regiment while stationed in the Alleghanies, in 1861, occurring after some weeks' exposure in camp, especially to unaccustomed night air, was alleged to be due to this agency. The popular mind to-day gives credence to this mysterious influence, as it always has done for hundreds of years. Says Cooke, in a recent work on Virginia, speaking of the early settlers on the James River in 1607: "With July came the sultry dog days of a southern summer, and the marshy banks of the river, sweltering in the sun, sweated a poisonous malaria which entered into the blood of the English. The whole colony was prostrated by a virulent epidemic." Thus, as at tide-water two hundred and fifty-four years before, was the origin of a disease assigned to the same causation in the mountains in 1861. In both of the instances named men were suddenly transferred from civil life to an out-door existence, in which little care was taken to properly habituate themselves; sometimes they were idle and inactive for weeks and months, until some emergency called forth their utmost exertions, leaving many greatly exhausted. As a class they were without self-restraint in respect to both food and hygiene. Were not physical influences manifestly the cause of whatever affection these people had, rather than mythical ones? A gentleman competent to give an intelligent opinion, and who has long practised medicine in tropical South America, once said to the writer, in discussing this subject, that it was his belief that their severe fevers might justly be regarded as an aggravated form of catarrhal inflammation.

The confounding of symptoms alleged to arise from so-called malarial poisoning with catarrhal inflammation (inclusive of nervous phenomena so often present) seems to have for its origin the belief that a malignant miasm exists in the emanations arising from decaying animal or vegetable matter, sewer-gas, stagnant water, etc., or is disseminated by the pollen or effluvium of plants. It is to be regretted that the accumulated literature of this subject, embracing the labors of writers for many centuries, cannot by incontestable evidence establish these tenets; proof of the existence of malarial poison, according to a contemporary authority, lies mainly in the alleged fact that the sickness it causes yields to the administration of quinine.

In accepting the miasmatic origin of disease, it has been found convenient to explain its morbific influence through zymotic action, and more recently the microbic theory has been advanced; but whether the "fermentation" of zymosis and the presence of bacteria in the blood are not a product rather than a cause of disease, may well be believed.

The neglect of cleanliness, or, more broadly, of sanitation, is fraught with much evil; but while fully recognizing the danger to health from decomposition of animal and vegetable matter, would not a healthier sanitation prevail were the popular "fetich of the sewer," to which such quantities of quinine are sacrificed, put aside? How often has house-drainage been laid under unjust suspicion in pursuit of this imaginary evil; the wall-paper of the sick-room even torn down in the search after the sewer-pipe has been overhauled, or the house abandoned entirely? How often have worry, dissipation, and exposure, lowering the tone of the nervous system, overtaxing the stomach with alcoholic drinks and indigestible food taken at all hours, breathing the poisonous air of the ball-room, theatre, and the like—probably continued for a "season"—been the cause of sickness unjustly attributed to defective drainage?

It may be well to consider the causes of catarrh of the head somewhat broadly, since the belief has taken deep hold on the minds of many that the malady is purely local; when the influences lying behind local manifestations are thus recognized, it is believed a more rational treatment will prevail. Among the causes are:

Meteorological influences. — Lightning stroke, sunstroke, and congelation are not, of course, in the ordinary sense, to be considered as causal; it is the less or entirely inappreciable, and hence unexpected, variations in meteorological conditions that interest us, more especially because they are liable to be underestimated or overlooked entirely. These changes consist in variations in thermal, electrical, and aqueous vapor tension, inclusive, consequently, of the relative amount of sunlight, oxygen, ozone, etc. The most important of these, and doubtless influencing them all in greater or less degree, is the heat radiated from the sun. Animal and vegetable life upon the earth's crust derive their vitality

from this source. It is the struggle against the undue loss of this heat through radiation from the earth's surface, on the one hand, and the avoidance of an excessive supply on the other hand, in order that a healthful equilibrium may be maintained, that concerns the sanitarian. Circumstances have placed man alike in warm and cold climates, as well as in the more favored temperate latitudes; the latter is most favorable, since out-door life may be enjoyed to a greater extent than elsewhere. It behooves one, therefore, in considering the causes of catarrhal inflammation, to take into count weather vicissitudes due to natural causes. A study of meteorological physics, so far as understood, will make known the natural laws regulating heat, electrical and aqueous vapor tension, of the movements of wind and water (trade and anti-trade winds and ocean currents); the proportion of oxygen, ozone, etc., under varying conditions.

The functions of life for the most part must be carried on in an environment of ever-changing physical forces. We may be said to live amidst ceaseless aërial cyclonic movements of greater or less energy, since the air is ever in motion; these storms—sometimes one following the other, sometimes moving along in an irregular manner together—traverse to a greater or less extent the entire continent, disturbing a varying area of territory. As the cyclone constituting the ordinary thunder-storm advances, there is always a higher temperature in front than in the rear—"the warm air in front," according to Mr. Abercromby (*Nature*, 1885), "having a peculiar, close, muggy character. The cold air in the rear, on the contrary, has a peculiarly exhilarating feeling." These conditions are quite independent of the thermometrical condition.

The following puzzling experience is illustrative of the effect of these influences; it occurred in the writer's early experience in practice. The patient was a man, aged forty-five, whose general health was fair; on entering the sick-room I found him gasping for breath. The heart was beating tumultuously, and his nervousness was painful to witness. He had been attacked with these symptoms on the approach of a thunder-storm which was then prevailing. His wife, who showed no alarm, informed me that he always suffered in this manner during storms, and that recovery was always speedy and complete as soon as the weather cleared.

Sudden and extreme changes in altitude also give rise to peculiar disturbances; persons on arriving in this manner, by rail, at an elevation of some sixteen thousand feet in the Andes, are liable to experience very disagreeable sensations, due to the sudden withdrawal of atmospheric tension. Besides the cardiac failure and pulmonary derangement produced by the transition, congestion and anæsthesia of the skin, cramps, and other nervous disturbances are experienced, known in South America as aire. Similar to phenomena occurring in very much *rarefied* air are those witnessed in persons on coming out of the highly *condensed* air of submarine caissons; in either the sudden disturbance of equilibrium of density causes undue nervous strain.

It is, however, the much more slight variations associated with storm movements that probably give rise to the nervousness experienced by certain individuals. The writer has been informed by a number of his patients that they cannot long endure a sea side residence in summer, even in so agreeable a place as Newport, R. I., on account of the extreme nervousness apparently produced by an environment affected by wind that has swept rapidly over the ocean for a long distance. Besides the general nervousness experienced, there was irresistible somnolency at one time, and at another a total inability to obtain sleep.

I am not aware of any explanation of these phenomena being given, but I suspect that when the nervous system is impaired by exhaustion, its liability to undue excitation or depression by the causes alluded to is increased.

Thermal changes are yet more important than either electrical or barometrical. The rapid liberation of heat from the body of the strong generally arouses healthful activity, but it depresses the weak; on the other hand, the acquisition of a relatively great amount of heat is well borne by the former, while prostrating the latter.

Prolonged exertion in extreme summer heat gives rise to nervous prostration or irritability; this is especially liable to occur during the "dog-days" of late summer, when even slight exercise is fatiguing and attended with perspiration. A draught of air is then, according to the Spaniards, *una facada*, a knife-stab, so dangerous is it regarded. But, as would be expected, exposure to night air when the sun's heat is withdrawn, is particularly dangerous to the susceptible. It is then that *sudden* cooling off, especially in damp clothing, and while the body is overheated, that catarrhal inflammation may occur.

It was long ago shown by Dr. Wells, that when the sun has set the earth's surface becomes quickly cooled by radiation, and the air immediately above becoming too cold to retain its aqueous vapor in a state of suspension, the moisture is therefore rapidly deposited upon the earth in the form of dew or frost, according to the lowness of temperature. It will be observed that dampness often shows itself upon the turf sometimes before the sun has sunk, and from this on the dampness and chilliness of the under stratum of air increases more and more up to a certain point. The intelligent class of natives of the tropics practise much caution to avoid the deleterious effects of this exposure, but notwithstanding their prudence, catarrhal affections of a severe character prevail. This result is less surprising, however, when the effect of prolonged summer heat in producing apathy and inertia—totally preventing exercise, and thus increasing susceptibility—is considered.

Night air at sea is likewise to be avoided, since even the general bracing effect of ocean air by no means insures immunity from catarrhal trouble.

The more decided catarrhal attacks are, of course, well known to be ushered in by chill, with more or less nervous disturbance; sometimes a local manifestation also occurs, as torticollis or a "crick" in some other region. Usually, however, we have to consider the influence of slight impressions only on the nervous system; these have been distinguished as a "shock" or a "stab," although but a slight immediate effect is experienced. In the end, however, very decided phenomena are produced through the vaso-motor system of nerves. A susceptible person may not remain with uncovered head for many minutes in the dew-laden tropical night air without sneezing or even contracting rhinitis. Greater or long-continued exposure, especially in run-down persons, may be followed by ague, dengue, neuralgia, or rheumatism, according to the patient's idiosyncrasy or susceptibility. Of course, the hardy native "of the soil," so to speak, becomes acclimated to vicissitudes by long residence, and even the languid and more unstrung resident acquires immunity not to be enjoyed by strangers.

Thermal variations, otherwise inappreciable, visibly affect the system when run down; thus, in a six-days' summer voyage from Suez to Aden, says Medical Director Delavan Bloodgood, U. S. N., in a letter to the writer, the temperature was seldom lower than 100° Fahrenheit, day or night; on entering the Gulf of Aden, however, a breeze encountered, only a few degrees lower, produced such a chilling sensation that the passengers found an increase of clothing absolutely necessary. My informant recalls now, after many years, the chattering of his teeth on that occasion, and the discomfort lasted for several hours. It is not unusual under these circumstances to experience an immense increase in urinary secretion, andt he ship's surgeon in consequence always receives the visits of a large number of surprised, if not alarmed, passengers. Experiences of practical interest bearing on this point are common enough to travellers. Thus Stanley found, after travelling for some considerable time in the relaxing climate of equatorial Africa, that warm clothing,

including an ulster, was comfortable in July, when the minimum temperature was 63° F.; and the draughts of wind sweeping down the gorges, though not decreasing temperature thermometrically, added greatly to the feeling of "miserable chilliness." The catarrhal manifestations which seemed to prevail on the Congo under those circumstances were of the gastric variety. Mr. Crawford, a gentleman engaged in selecting a railway route across the Pampas during the hot months, notes the rapid changes in temperature on La Plata; a sudden fall from great heat to 26° F., freezing ice in the tents on one occasion, and at Mercedes on another, after an intensely cold night, the thermometer registering 34° F., temperature rose to 107° F. in the shade at 4.30 P.M.

Forbes, while travelling in the Eastern Archipelago, found the natives in Sumatra going about, and even sleeping, in all weathers, nearly naked, and enjoying good health; but almost at once succumbing to the low temperature of mountain heights, often actually dying before they could descend. Mr. Forbes, in his admirable work "The Wanderings of a Naturalist in the Eastern Archipelago," states that at an elevation of 10,562 feet up the Dempo, the midday sun was almost unendurably hot, the hands, face, and neck being scorched the moment they came into the sunshine, though a cold wind was blowing; and the thermometer registered only 63° F. When the sun began to decline, however, the temperature fell rapidly; at sunset it was 47.2° F., and for comfort he was obliged to put on triple suits of clothes.

"When at four o'clock next morning," says Mr. Forbes, "I went out into the Sawah, though the thermometer registered 47° F. (the lowest reading of the night was 42° F.), the air, which was perfectly still—its silence, indeed, almost overwhelming—felt absolutely free from rawness, in marked contrast to what I had experienced at sunset under almost the same reading of the thermometer."

Mental exhaustion alone, without open-air exposure, is very often a cause of head catarrh; yet may one sleep in a cold airy apartment, when not overheated, without risk, and patients with high temperature, unless sweating excessively, get on best with such surroundings.

Causative influences like the foregoing finally prevent healthful equipoise between the different organs, and, in consequence of this, elimination is defective. Along with defective nutrition a perverted state of the nervous system obtains: its tension on the one hand is depressed, or on the other hand increased. At either extreme, or in vibrating between them, peculiar phenomena present themselves; thus periodical disturbances influencing temperature may characterize catarrhal fever, or they may manifest themselves as "nervous explosions" at irregular intervals. Certain subjects become known as "nervous," and are liable to uncontrollable sighing, weeping, outbursts of ill-temper, and other emotional manifestations. Others thus illy-balanced indulge inordinately in stimulants, or food, or sexual excess. It is a notable fact that such nervous persons are extremely subject to catarrhal inflammation, which is liable to take on nervous characteristics. Thus, with bronchitis appears the suffocating spasm of asthma, and with rhinitis the violent irritation and sneezing of hay-fever. Catarrhal neuroses, once acquired by the more susceptible, increase by long continuance to a degree never experienced by less sensitive persons. These local disturbances of the mucous surface are comparable to neuroses of the skin, as zoster and pruritus, where cutaneous burning and itching are caused by reflex action.

Where the asthmatic habit exists, meteorological disturbances, excessive physical exertion, undue mental excitement or depression, cold winds and dust, excite spasm and cough. The sight of dust, even without inhaling it, will excite spasmodic cough—indeed, almost every asthmatic has his *bête noire*, which may explain the whimsical origin of asthmatic spasm in some cases.

In the disordered olfaction of hay or rose fever, the odor of the rose and other objects is compared to the irritation of pepper applied to the Schneiderian membrane, and as in asthma, various dusts and odors cause distress.

Head catarrh often begins very early in life, and continues a long time before the subject is brought to the physician's notice. In fact, it is usually neglected until marked deafness has occurred. The neglect of nasal catarrh is often due to the indifference to the slight discomfort attending impairment of smell, since at best this function is less perfect from disuse or want of cultivation than that of the other special senses. In a few instances I found the sense of smell most acute, resembling that of many of the lower animals, where its importance in the economy is scarcely second to hearing and seeing.

The rhinitis of hay and rose fever is often found to stand in a causal relation to otitis, affecting the ears either by extension of the inflammatory process from the naso-pharynx up along the Eustachian tube to the tympanum, or through reflex sympathy of the nerves.

Sympathy of the nerves.—In certain conditions of the system the nerves become exceedingly impressible to excitation; thus the irritation produced by the introduction of a speculum or a probe into the external auditory canal will excite coughing, or a desire to swallow, and various other sensations in the nose, pharynx, or larynx. Many persons can locate the seat of local irritation thus

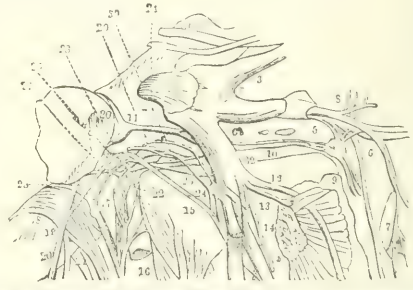

FIG. 2.—Diagram of the Tympanic Plexus (Ranvier). 1, Oculo-motor nerve; 2, trigeminus nerve with the Gasserian ganglion; 3, first branch of the trigeminus nerve; 4, second branch; 5, entrance of the same into the spheno-palatine fossa; 6 and 7, superior maxillary nerve; 8, spheno-ethmoidal nerve; 9, descending palatine nerve; 10, Vidian nerve; 11, large superior petrosal nerve; 12, buccinator nerve; 13 and 14, pterygoid nerve; 15, chorda tympani nerve; 16, carotid plexus of the sympathetic; 17, petrosal ganglion of the glosso-pharyngeal nerve; 18, 19, and 21, vagus, accessory nerve of Willis, and hypoglossus; 20, facial nerve; 22, nervali carotico-tympanici; 23, tympanic, or Jacobson's nerve; 24, small superficial petrosal nerve; 25, nerve of the tensor tympani; 26, tympanic plexus; 27, branch for the oval window; 28, branch for the round window; 29, large, deep-seated petrosal nerve; 30, branch for the Eustachian tube; 31, division of the Vidian nerve into its two branches; 32, anastomosis of fasciculus of the Vidian nerve.

propagated in the ear in some particular spot in these parts, the sensation being described as "burning," "tickling," and the like. *There is very often an increase of the secretion of mucus in the spot thus irritated.* When the throat is in a diseased condition, the reverse of the above often takes place, and the ear may then become affected. When nerve-tension has been long disturbed in this way, reflex phenomena are easily excited; continuous aural, nasal, or dental irritation, even if imperceptible, may affect one part or another, until nutritive (trophic) changes are brought about; slowly progressive aural catarrh finally producing deafness before the patient himself is aware of any morbid action going on. The tissues involved in catarrhal inflammation of the middle ear "consist of a membrane which performs the double duty of mucous membrane and periosteum. The sensitiveness of this structure is extremely great, for it is not only richly supplied with blood-vessels, but also wonderfully well provided with sensory nerves. These latter compose the tympanic plexus, a diagram of which is here shown. This anastomosis derives supplies from sources most extensive; thus by means of branches from the otic ganglion the inferior maxillary nerve is brought into intimate relations with it, and the petrosal ganglion of the glosso-

pharyngeal nerve supplies the tympanic branch, or Jacobson's nerve, which constitutes a large portion of this anastomosis. The carotid plexus of the sympathetic sends a branch to the glosso pharyngeal, and thus establishes a communication between the ear and the superior cervical ganglion of the sympathetic nerve. Through Meckel's ganglion, by means of the Vidian nerve, the superior maxillary of the fifth pair of nerves also is connected with the tympanic system. Besides these there are other connections which may be seen by consulting the diagram."[1]

This extensive nervous connection brings the ear into sympathetic relationship with disturbances in various parts, as the brain, stomach, heart, genito-urinary organs, and cutaneous surface, as well as with other parts already mentioned.

Catarrhal affections of the ear.—From an etiological point of view catarrhal affections of the upper air-tract should be considered as a whole, although the ear, olfactory region, and the various cavities and sinuses of the head may become independently affected. Catarrhal affections of the ear are most frequently met with in the chronic form and in connection with continuous head catarrh; recurrent exasperations ("colds") frequently marking a more or less rapid decrease in hearing power. One ear, usually the left, is found to be first affected, and in the end most impaired.

Aural catarrh, especially the subacute variety, beginning as early as the first month of infantile life, may give rise to total deafness, the proliferation of connective tissue about the articular surfaces of the ossicles producing fixation. Acute purulent inflammation at this period, however, usually leaves the hearing less affected, unless the process become subacute or chronic. The purulent variety may prove fatal; unsuspected ear disease, in fact, is frequently shown, by post mortem examination, to have been the cause of death in young infants, when symptoms of brain disturbance only were recognized during life.

The relations of dentition to aural trouble are very important in infancy; before puberty this process is most active, causing often great nervousness, especially in girls overworked in schools or shops. The catarrhal fever, to which this class of persons is subject, may simulate typhoid fever, for which it has been mistaken.

Adolescents sometimes get their wisdom-teeth with difficulty—indeed they are often not cut until the patient is thirty years or more of age. In consequence of the aural irritation excited through nervous sympathy in such cases, subacute and chronic catarrh of the middle ear, giving rise to extreme deafness, is of frequent occurrence; deafness may come on so gradually that the patient is unaware of its existence until its progress has been marked. Dentition is thus liable to be an important factor in catarrh of the head, and should never be overlooked in treatment. The retention of pulpless teeth should be avoided, especially in persons wanting in nervous tone.

Overworked shop-girls, living under faulty hygienic conditions, having dental irritation, sexual disturbances, and the like, are extremely susceptible to aural catarrh, giving rise to extreme deafness.

Children's catarrh (acute) of the upper air-tract may be ushered in with chill, followed by fever and more or less local irritation, manifested by sneezing, a down-pour of fluid from the nose, and tinnitus aurium as the ear becomes invaded. The fluid profusely secreted by the conjunctival mucous membrane, and that flowing from the anterior nares, often excoriates the cheeks and lips, and later on there is frequently an eczematous eruption at the seat of irritation. The tympanal secretion is sometimes so great that the drumhead gives way and allows the pent-up fluid to escape. The aural discharge also may be the cause of dermatitis, etc., about the external auditory canal and auricle. At first the secretion from the nose and ears may be tinged with blood, but in many cases it soon becomes mucoid, bland, and ropy, and there is a tendency toward a regressive course and spontaneous recovery. In some cases, however, there is a greater tendency to purulency and chronicity; this is especially liable to occur in cachectic, run-down children having chronic head catarrh, difficult dentition, etc.

When serum only, or thin mucus, is poured out into the middle ear, it is frequently carried off into the throat *via* the Eustachian tube, but where the swelling closes the tube, or the mucus is too thick to escape, an accumulation soon takes place, distending the drum-head, and giving rise to earache. When the drum-head has been thickened, and does not give way readily, the distress may become almost unendurable. In the more severe examples of acute aural catarrh the principal seat of the trouble will be found in the attic of the tympanum, where swelling of the mucous lining prevents drainage either down into the atrium of the tympanum or through the Eustachian tube, the pent-up fluids seeking an outlet through the membrana flaccida, which often becomes greatly distended. The secretions, if not liberated, finally burrow along underneath the lining of the superior wall of the external auditory canal, forming a sac of greater or less size, which sometimes entirely conceals the *membrana tympani*. At the same time the *antrum mastoideum* and adjacent cellules are liable to invasion, as well as the periosteum externally.

Subacute aural catarrh, causing great deafness, sometimes occurs consecutive to scarlet fever or measles in children; secretion from the tympanal mucous membrane may be slight, the drum-head may remain intact, and deafness only suspected when the child is found to be backward in learning to talk.

While persons in health quickly rally from head catarrhs, experiencing no harmful result, in delicate children and broken-down and decrepit subjects the disease is liable to assume a chronic form; where the ear is thus affected, recurrent exacerbations are liable to be followed by a decrease in hearing. Concurrent gout, rheumatism, scrofula, consumption, or other constitutional disease increases the gravity of the trouble, and in the two affections last named, as well as in subjects of diabetes mellitus, the tendency to destructive purulent otitis media, with rapid disintegration of the *membrana tympani*, and profuse otorrhœa is marked. In rheumatic and gouty catarrh, however, there is seldom any great amount of pain, the effusion is often serous in character, and no tendency to suppuration exists, the principal seat of inflammation being confined to the attic, involving to some extent the membrana flaccida and other neighboring parts rather than the atrium. These cases are characterized by chronicity, and sometimes a collection of straw-colored serum can be seen behind the drum-head, where it may remain for a long time, displaying air-bubbles when the drum is inflated.

In scrofulo-syphilitic subjects the deeper structures of the ear and nose, including sometimes even the osseous tissue, are liable to be affected; and in syphilitic catarrh, exacerbations are sometimes attended with very pronounced and sudden deafness.

Secretion in catarrhal inflammation is generally characteristic; thus the outpour of fluid from the inflamed mucous membrane of the nose in children, after the feverish stage at the onset, is profuse, as it also is in recurrent rhinitis in adults, notably in hay fever. Incrustations of inspissated muco-pus in the caverns of the nose, especially where a deviation in the septum exists, are seldom seen before puberty; but in chronic catarrh in cachectic persons, or in advanced life, where the mucous membrane enveloping the erectile tissue of the nose has become atrophied, evaporation of the scanty secretion leaves inspissated crusts, which soon become fetid. There is an intermediate stage when mucous secretions become very tough on drying, and are worked out with

[1] Vide author's paper, Earache in Children, Medical Record, May, 1885.

difficulty. Secretion may consist of mucus principally, or it may become sero-mucous, sero-sanguinolent, muco-purulent, purulent, or otherwise combined, according to circumstances.

Inflammation of the mucous membrane of the tympanum, mastoid antrum, or pneumatic cellules of the temporal bone, take on secretory processes similar to the above; the presence of tough mucus affords an explanation of deafness through interference with the movements of the transmitting mechanism; and where sudden and extreme deafness takes place, as in some forms of non-purulent aural catarrh, especially in syphilitic subjects, there is probably infiltration of a particularly adhesive nature, causing rapid fixation of the ossicles. The most marked non-syphilitic examples I have seen were in persons residing in the tropics. Two cases among the latter are particularly instructive. They were non-syphilitic.

Case I.—A gentleman, aged forty-five years, came to me a year ago with the following history: He had resided in Rio, Brazil, some thirteen years altogether, having taken in the meantime two vacations of eighteen months each, during which he visited Europe and this country. During his residence in the tropics, he was for some time under severe mental strain, but passing the warm season in the mountains of Petropolis, the summer residence of the court, at an elevation of some three thousand feet. While so run down, the extreme and sudden variations in temperature were very trying; succeeding to intensely hot and dry days, were damp nights some 20° Fahrenheit cooler. Not having learned of the perils of *el sereno*, the fatal night air, he was less prudent, in respect to exposure after sundown, than the natives, who are careful to protect themselves with warmer clothing, and avoid uncovering the head needlessly for a moment even. He finally contracted severe head catarrh. There was, at first, a sense of great heat and discomfort in the nose, perversion of the sense of smell, especially on first rising in the morning, when everything had the odor of burnt meat. There soon was a profuse down-pour of fluid from the head, which was mixed with blood. On the frontal sinuses and other cavities becoming invaded, the head felt "hot and dry." These symptoms continued for some time. The ears were early involved, and as the disease progressed he became *rapidly very deaf*. Distressing tinnitus accompanied the other symptoms. He was for a few days so deaf as to be unable to converse, but before long some improvement took place; there was no marked improvement in the head catarrh, however, until he left the tropics; and when I saw him subsequently, he could converse with difficulty, in an ordinary tone of voice, at a distance of six or eight feet. Under the favorable influences of the climate in New York, he improved very much under treatment.

The next case is similar to the above.

Case II.—An English gentleman, thirty-five years of age, residing in Venezuela. This patient, a person very much over-worked, in April, 1884, made a three weeks' journey into the interior of the country, during which he was much exposed to an almost continuous rain-storm. He escaped the prevailing fever as he had done hitherto, during twelve years' residence in tropical South America. During his stay with a friend in the country, he sat one morning after breakfast in the corridor of the house *without any coat*. After dinner, the same day, while engaged in conversation he *suddenly* had a most profuse flow of fluid from both nostrils and the eyes, which lasted for some hours. The attack was severe and was accompanied with much coughing. It was feared that this would prove to be a precursor of the "fever" of the country, but the more disagreeable symptoms passed off by the next morning. Head catarrh, however, continued, the tympanum became affected, and there was almost total deafness. A disagreeable sense of fulness in the head, and dryness of the upper air-tract characterized the course of the disease and, in fact, still remained when the writer was consulted.

Treatment.—In the treatment of catarrhal inflammation of any particular part of the upper air-tract, attention should be directed to the condition of every other part; aural catarrh, for example, is not unlikely to be associated with rhinitis. Where indigestion and faulty assimilation are provocative of rheumatism or gout, etc., or, in fact, where any disease may stand in the relation of predisponent or excitant, these factors must not be overlooked, and when the patient's interests require it the valuable aid of other practitioners may be sought.

In no affection is attention to hygiene so important etiologically, and hence the questions of food, clothing, bathing, exercise, and ventilation should receive prompt attention. This will be found a most difficult part of the physician's task, especially as regards children and invalids, since the convenience and comfort of parents and nurses is too often consulted to the detriment of the patient; thus are outings curtailed or prolonged unduly, and heating and ventilation arranged to suit the well rather than the ailing. Open air exercise daily should be insisted upon as far as children are concerned, and when inclement weather prevents going out the nursery may be converted, for the time being, into an open air play-ground by throwing open windows and doors, children (or invalids), being suitably clad. Too often is cloudy, threatening weather an excuse for neglecting exercise.

Out-door life for invalids should be regulated, both as regards preventive and curative treatment, by the patient's tolerance for exercise without undue fatigue.

Protracted in-door life during the dark, damp, cold, short days of winter tends to very much lower the tone of the system; it is after this depressing experience, and on the return of milder weather, that incautious exposure causes catarrhal troubles. Delicate persons, especially when over-heated, should avoid exposure when rapid evaporation of snow and ice occurs during a winter "thaw," since even slight (and usually unconscious) chilling of the body causes mischief then rather than the succeeding cold "snap," the effect of which is to tone up the system. It is said that voyagers returning from high latitudes are extremely susceptible to catarrhal affections on returning suddenly to temperate regions.

Health requires that exercise be taken in very cold weather, provided the proper quantity of food is consumed. Now, the animal heat derived from food with difficulty compensates for the immense quantity lost through the escape of heat into space by radiation. The problem of maintaining an equilibrium between these two diverse processes is therefore difficult of practical solution; thus exercise is impeded in a measure proportionately to the means employed in retaining bodily heat by means of clothing, etc. If the escape of heat is prevented by non-conducting clothing, impervious rubber-cloth, the skins of fur-bearing animals, and the like, escape of insensible perspiration through evaporation from the body is also interfered with, and the clothing becomes saturated with moisture—an exceedingly disagreeable and unhealthful condition. The very general introduction of rubber-cloth and fur garments in our temperate climate is to be greatly deplored, since the bodily temperature is too much increased by their use. In regard to the maintenance of a proper bodily temperature, it may be said that everyone must, in a measure, regulate this by the changes in wrappings suggested by his own sensitiveness, rather than the readings of the thermometer.

The advantages of travel and change of climate have long been recognized, and it is particularly notable that where catarrhal neuroses affect residents of cities, immunity may be enjoyed during a sojourn in the country, and *vice versa*; asthmatics are even permanently cured in this way. The most striking effects, perhaps, follow

changes to pure sea or mountain air, but the writer has known of a number of instances of asthmatics being cured on leaving the great interior valley of the Mississippi to reside in New York City.

The inconsiderate advice sometimes given to patients of delicate constitution while ill, to hurry away from accustomed comforts to some favorite region, may prove exceedingly hurtful. The endurance of patients differs greatly; one may become robust in the Adirondacks, while another cannot endure the exposure of camping out. Patients, therefore, should be well informed in respect to the requirements of the particular spot to which they are sent; for example, they will find that natives of the tropics require thick woollen clothing during their short winter, although the thermometer may register 60° F. only, while those of high latitudes, where the sun's rays during their brief summer are exceedingly oppressive at 60° F., *per contra*, may swim in the ice-cold water with much pleasure. The native Esquimo through much exposure become inured to the dreadful Arctic winter, *even suffering with heat when the temperature rises above the freezing point;* cold weather and exposure, says Schley, in the narrative of the Greely rescue expedition, have no terror for them.

In the tropics, sensitiveness to sudden exposure to air a few degrees below the customary temperature, has been shown to give rise to chilliness; on the other hand, sensitiveness to moderate heat gives rise to equally painful sensations to persons long inured to Arctic cold; thus a scalding sensation is imparted to the skin by the contact of the warm blood flowing from the whale and walrus when slaughtered.

For the greater number it would seem that a knowledge of their own environment, together with a study of the conditions best suited to their needs, is of much greater importance than the discovery of sanitaria, at best available to but few. Indeed, it is useless to seek a perfect climate where catarrh is not found; we can only recommend the best average climate suited to a particular case. Patients from the North find needed rest in the languid life of the South, while Southerners are benefited by the bracing air of the North. Moreover, it will be found by experience that favorite resorts have their off-seasons; for example, Nassau, usually the most charming of winter climates, was during the past winter (1884–85) so disagreeable from the cold and humidity, that many of our patients sent there for the winter were compelled to leave before the season was over. If the invalid go to tropical climes, aqueous vapor is liable to be found in excess the year round, the humidity of the summer interfering with healthful escape of insensible perspiration, and that of the winter conducting away bodily heat too rapidly.

The influence of aqueous vapor in the air is important: Tyndall, says Stewart (*Nature*, vol. ii., 1885), has called attention to the fact, that aqueous vapor being transparent for rays of high temperature, does not stop but a small portion of those which come to us from the sun; but being comparatively opaque for rays of low temperature, it stops the radiation into space from the surface of the earth. In other words, it acts as a cloud in preventing refrigeration which accompanies dew. In regions, however, where the air is very dry, the nights are intensely cold, owing to the uncompensated radiation into space. In Central Asia and in South America, as cited by the writer, water is often frozen after the sun is below the horizon.

The treatment of catarrh of the upper air-tract implies the management, to some extent, of all the troubles about the head, since nearly every affection of the ears, eyes, nose, mouth, and nervous system of this region is generally more or less associated with a departure from the healthful condition of the mucous membrane of this tract. There is too often a demand for an exclusively local treatment, however harsh, which, in attacking a local manifestation, promises to strike down the evil, rather than a rational method which may remove the cause. It is desirable, of course, to get rid of the results of disease, but this will not always affect the cause; in other words, the root of the evil cannot be reached by local treatment alone.

At the onset of acute catarrhal inflammation of the head, local applications, consisting of weak alkaline solutions in water as hot as can be comfortably borne, are soothing, and answer to cleanse the accessible parts when secretions require removal by mechanical means. More rarely are sedative applications required, but where the tonsillar crypts are the seat of chronic inflammation, they may be touched with solutions of nitrate of silver, tinct. iodine, etc. In the chronic form of catarrh, beyond cleanliness, there is but little need of local applications; astringents, however, are sometimes beneficial, especially weak solutions of nitrate of silver, sulphate of zinc, acetate of lead, and the like, or vegetable astringents. These may be applied by means of atomizing apparatus, brushes, or cotton-wool mops; the latter are convenient and have the advantage of being cleanly. Solutions can also be introduced with a syringe, or sniffed up from the hand.

The nasal douche is a most efficacious means of cleansing the naso-pharynx or of applying medicated washes, but it is by far too treacherous to be safely employed by the patient himself. Even sniffing up solutions, or the insufflation of powders, are to some degree open to the same objection, namely: the danger of passing fluids, etc., up through the Eustachian tube into the ear and causing inflammation.

As a rule, I have not often found the nasal mucous membrane to be improved by the application of irritants, which ordinarily give rise to sneezing and coughing when accidentally inhaled, whether employed in dry or humid form, and I believe their indiscriminate use is to be deprecated. The heroic methods often resorted to in treating irremediable, but yet persistent, patients, likewise are usually unjustifiable; the employment of the galvano-cautery, wire snare, écraseur, or strong acids for the removal of structures in the nasal region, has brought out some very energetic methods, which, if safe and proper in skilful hands, are certainly liable to much abuse, and are known to have done positive injury to the nose, as well as set up serious trouble in the ear.

Hypertrophied tonsils, whether obstructing respiration by their size or interfering with the action of the muscles of the upper respiratory tract, should generally be removed.

The treatment of rhinitis, which is so important a feature of hay and rose fever, may often, with advantage, include brushing or spraying the irritated or inflamed turbinated bodies once or more daily with a two to four per cent. solution of cocaine. Tolerance, which sooner or later occurs, lessens its effect finally, and in some cases it does no good.

Atropine ointment, rubbed over the bridge of the nose and the frontal sinuses, often affords great relief; care should be taken, however, to prevent its entrance into the eyes.

Catarrh of the head, especially the acute rhinitis of hay and rose fever, which is most liable to come on in late summer or in the beginning of autumn, seems to depend on the excitability of the nervous system frequently following protracted hot weather, and the neglect of exercise, and it rapidly disappears again under the toning-up influence of cold weather. Since worry and depression of spirits are to be regarded as predisponents in the nervous catarrhs, it is well to remember the advantages of pleasurable excitement, which in asthmatics dispel paroxysms like magic. And, moreover, the "habit" sometimes disappears altogether after the more excitable period of life—the patient, so to speak, having "outgrown" the trouble.

The mucous membrane constituting the inner lining, as compared with the dermic layer forming the outer

covering of the body, offers but little resistance to impressions through the nervous system; inflammation of either, however, often gives rise to sympathetic fever. Perversion of the sexual sense may, in one instance, cause an abundant display of acne upon the skin of the face, or it may expend itself, so to speak, upon the mucous membrane of the head. Sometimes both dermic and mucous surfaces are affected at the same time.

In the internal treatment of acute catarrh of the head the various forms of mercury are most beneficial, especially in the affluent stage; indeed, so long as there is no tendency to suppuration, but rather an inclination to a regressive course, mercury may be used throughout. There is, however, a choice in the form of this drug; one may use hydrargyrum, rubbed up with sugar of milk, which is somewhat similar to quicksilver treated with chalk, only in the former a much finer division of the drug is made. The hydg. chlor. cor., hydg. chlor. mite, and the hydg. cyanidum, are useful forms of the remedy. I myself usually employ the second or third decimal trituration in powder or tablet form, using the cyanide in smaller doses than the others. With the above, given every two or three hours, bryonia alba is a useful adjunct, or this may be given alone after the mercury has been omitted. Where there is pain or nervous irritability, aconite, gelsemium, belladonna, or pulsatilla, are indicated in minute or small and frequently repeated doses; these are particularly indicated where there is fever. Belladonna alone, or with aconite, is specially indicated where tonsillitis is present; where dryness of the throat or increased temperature are observed, they should be suspended for a time. Pulsatilla having no cumulative tendency, is particularly well adapted to children and infants. Where fever arises from the nervous irritation of catarrh, large doses of quinine are not always so much indicated, as minute doses of aconite, frequently repeated. Where purulency threatens or exists, the calx sulphurata may take the place of mercury. In the employment of medicines a due regard for emergencies requires that their use should be prompt in the acute stages, and omitted, from time to time, in order to ascertain what their effect has been. The more profound anodynes are sometimes indicated by the severity of pain; they should, however, only be employed in a tentative way, since they mask symptoms and interfere with nutrition.

In cases where rheumic, gouty, or neurotic tendencies exist, the employment of quinine or rhus toxicodendron is advisable, the former in from two- to five-grain doses, repeated once or twice daily for adults at the onset; the latter, largely diluted, may be longer continued. Diathetical treatment in general need not be alluded to here. Under this treatment, and the enforcement of necessary rest and other hygienic measures, I have seen inflammation of the ears, nose, etc., quickly disappear. The ear, however, frequently requires special treatment after the general subsidence of head catarrh. The aural mucous membrane requires the gentlest management, especially in delicate persons and in children; in the acute stage, more especially in *otitis purulenta acuta*, there is always danger of increasing, rather than abating, the inflammation by vigorous measures. Secretions in the external auditory canal should be only occasionally removed by gentle syringing, but frequently wiped out with absorbent cotton-wool, which takes up serous fluid and brings away the adherent mucopus. Decomposition of secretions should thus be prevented, and drainage secured. The moment secretion lessens one should be prompt in introducing dressings of boracic acid and calendula without unduly disturbing the healing drumhead. Later on boracic acid alone is sufficient, especially if chronicity threatens; at this stage it is sometimes advisable to stimulate the parts with calendula alone. When acuity is absent, and no danger of reopening the perforation exists, inflation of the ear is in some cases required.

The question of the evacuation of pent-up secretions in the atrium or attic of the tympanum can only be decided in any particular instance by careful examination, and a consideration of all of the features of the individual case; it is by no means always demanded, even when the parts are bulging or for the relief of that most uncertain of all symptoms, pain.

Since climatal vicissitudes exist wherever susceptible persons are found, catarrhal inflammation is a very general affection. Unfortunately, not until frequent exacerbations have left the ear or nose in an impaired condition, is advice sought, and we must then often content ourselves with preventive measures which will avert further destructive changes. The peculiarities of each and every case require careful consideration, the details of which cannot, of course, be given here.

In general it may be said, that in infancy the activity of the physiological processes concerned in development are often exhaustive; after puberty, the play of the maturing functions, especially the sexual, frequently are excessive; after adolescence mental and physical strain begins, and from this to middle age and beyond the struggle of existence is less easily borne, and worry becomes perhaps one of the most important factors of the affection under consideration. It is a notable fact that grief is accompanied, in emotional persons, with greatly increased flow of tears and nasal secretion—showing the influence of mental impressions on these parts. Treatment then should be adapted to the temperament and the age of the patient, and should be hygienic as well as medical. In chronic aural catarrh the treatment is necessarily less satisfactory than in the acute form. It is difficult to avoid disappointing the patient whose hopes and expectations are great, since we must often be content with moderate success only. Undue expectations must be met by frankness without discouragement. One's resources may be greatly tested in meeting the various symptoms which alarm the patient in advanced stages of aural catarrh; thus the greatest alarm is occasioned by the distressing symptoms of autophonia, vertigo, and sudden deafness.

ON RESPIRATORY NEUROSES OF NASAL ORIGIN (VASO-MOTOR CORYZA, ASTHMA).[1]

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

When I was asked, some weeks ago, to take part in the discussion this evening, on "Reflex Symptoms in Nasal Affections," it was my impression that I would be expected to talk, and not to write and read what I had written. A few nights since, I was told that it was desired that contributions to the subject to be discussed should be presented in written form. The consequence of this later knowledge is, so far as I am concerned, that my paper appears to me insufficient for my portion of a very large subject. I wish still to add a word, and it is that I have limited myself in my written remarks mainly to two subjects, hay fever (so-called) and asthma. I have done this advisedly—specially, I might add—because these affections are quite frequently met with, and they are diseases, therefore, which have a general professional interest. For this reason, any line of study, or clinical observation, which shall make clearer certain obscure points in their etiology and treatment, will unquestionably attract your attention and thought. With respect to reflex symptoms, which are rarely encountered, I have said but a few words. To speak of each local manifestation by itself would consume valuable time, and perhaps render my paper wearisome. Moreover, unusual cases in this connection, which we read of from time to time, may be often explained in the manner presently to be referred to when I speak of hay fever and asthma. Again, if what I say in this discussion shall throw any

[1] Read before the New York Academy of Medicine, January 21, 1886.

light upon the subject under consideration, it can only be in making reasonable and probable deductions from a judicial survey of the work of prominent observers in their special field. I may be permitted to add, that in my paper on hay fever (so called) which I expect to read before the Section on Laryngology, I have deviated from the path traced for me this evening, and have alluded more to my individual observation and experience than I have felt would be appropriate to the present occasion.

With these few preliminary remarks, I take up the subject assigned to me, viz., nasal reflexes, or reflex neuroses of nasal origin, pertaining to the throat and air-passages, and to general medicine. These may be divided into :

1. *Those affecting the respiratory tract.*—In these I include : (*a*) hay fever ; (*b*) pain and disordered function of the organ of smell ; (*c*) laryngeal cough, spasm of the glottis, alterations of the speaking and singing voice, recurrent laryngitis (Ingals : *Journal Am. Med. Assoc.*) ; (*d*) asthma, recurrent bronchitis, dyspnœic attacks.

2. *Those affecting the digestive tract.*—(*a*) Pain and disordered function of the organ of taste ; (*b*) reflex (?) uvulitis, pharyngitis, tonsillary enlargement, etc. (being *all* diseased conditions of the upper portion of the digestive tract) ; (*c*) gastric disturbances.

3. *Uterine disorders, and affections of the genito-urinary mucous membrane* (J. H. Mackenzie, Elsberg).

4. *Disordered cutaneous function.*—Localized facial sweating (Schmiegelow).[1]

Among these numerous affections, and as placed first on my list, and, also, in view of its great interest and importance, I desire to speak at some length of the affection so long and widely known as hay fever. And here I would immediately say that I am of the opinion that vaso-motor *coryza*, the name assigned to it by Dr. John H. Mackenzie, of Baltimore, is more consonant with a correct scientific interpretation of the disease, and it would be well if physicians were now to adopt it rather than the other misnomer. We are all more or less familiar with the combination of symptoms which constitute this periodical disease. The irritation and occlusion of the nasal passages, the paroxysmal sneezing, suffusion of the conjunctiva, frequent cough, the dyspnœa and oppression, form a picture which once seen is difficult to forget. Of the different theories which have prevailed in regard to its origin and nature, the old *pollen* theory, to which Blackley attributed so much value, mainly because he was a great sufferer from this special irritant, has within the present year been again brought prominently to our attention by its warm defence by no less an authority than Morell Mackenzie, of London. Suffice it to say that the *vitalized principle* of this small corpuscle, which was supposed to be taken up by the blood-vessels and to multiply in their interior, is no longer accepted by the vast majority of observers. Experts now regard it as a local irritant at times, and in certain individuals ; as very efficient in causing vaso-motor coryza ; frequently as *not* specially injurious ; occasionally as obviously innocuous ; and under all circumstances as merely *one* of a large number of special external agents, which may prove active in starting an attack when other conditions are present which are at once primary and essential.

In 1876, Dr. George M. Beard endeavored to show that *vaso-motor coryza* was a purely nervous disease ; that it was an affection peculiar to the conditions of our modern life, and indicated a hyper-sensitive and debilitated nervous system as its main efficient cause. Five years later, in 1881, and although Edson had already made allusion to the fact, Dr. Daly, of Pittsburg, showed conclusively that one very general, almost necessary, condition of the outbreak of this special form of coryza was the existence of catarrhal disease of the nose or naso-pharynx. Daly cured his cases by local treatment, and very soon his ideas and treatment were adopted by Roe, Sajous, Bosworth, Ingals, etc. Dr. John H. Mackenzie then brought to the attention of the profession the fact that in many of these cases there was evidently present a vaso-motor disturbance of the nasal fossæ. Despite these observations, however, it was soon shown that sometimes vaso-motor coryza existed without previous nasal disease, and that there were still other cases in which nasal disease under different forms had lasted for a long while, and yet vaso-motor coryza had never been developed (Cartaz). Nor was local treatment of the nose always effective in curing these attacks. Thus Sommerbrodt, who has been so successful in his treatment of the different neuroses of nasal origin by means of the galvano-cautery, failed notably in two cases of so-called hay fever. Sufficient cases, however, remain to show conclusively that *variable* reflex neuroses depend on *variable* intra-nasal conditions. These conditions may be—(*a*) permanent, and are then of the nature of true organic lesions ; (*b*) ephemeral, or passing—for example, a temporary hyperæsthesia and swelling of the turbinated bodies may be occasioned by cold, warmth, dust, light, psychical emotion, etc. Whenever the irritation is repeated a number of times, the swelling of the soft parts of the nose becomes permanent.

(*c*) Sometimes cough is only explained by intra-nasal conditions, and local treatment of the olfactory organ proves curative when other means have proved ineffectual. Seiler has reported such cases, although in one he attributed the cough to dropping of mucus into the larynx and from the pharynx, and not to the reflex influence of nasal irritation. A case of Mattei has also been reported, in which the envelope of a chestnut lodged in the nose produced spasmodic cough. Once this foreign body had been removed, the cough entirely ceased.

(*d*) Nasal polypi sometimes occasion attacks of asthma as well as other respiratory neuroses, and by their removal the dyspnœic paroxysms are permanently relieved. Voltolini first discovered this fact, which has since been referred to by many writers, among whom I may cite Morell Mackenzie, Terrillon, Fraenkel, etc. Besides polypi, other nasal affections, such as deviated septum, atrophic catarrh, chronic rhinitis, etc., produce similar results. Hunter Mackenzie has particularly called attention to this fact, so far as it related to atrophic inflammation of the nasal passages ; whereas Hack and Sommerbrodt appear to consider that turbinated hypertrophy is the main, if not the sole, condition present under like circumstances. Not only do conditions of atrophy and hypertrophy in the nose produce asthmatic seizures, but mere *irritable* conditions of these passages will produce a like effect. Sometimes, however, polypi, turbinated hypertrophy, deviated septa, atrophic rhinitis, chronic rhinitis, localized or general nasal hyperæsthesia, will exist for long periods, and are never followed by attacks of asthma. Again, I have known at least one case—that of a distinguished practitioner of a neighboring city—in whom several nasal polypi were removed, as they were believed to be the efficient factor in producing severe paroxysmal asthma. The polypi were snared off, and the nasal passages remained for a time relatively clear. Still, the paroxysms of asthma returned, and with quite as great intensity as previous to the operations for polypi. In this case the asthma undoubtedly depended upon an old bronchial catarrh, which was also allied with chronic changes in the cellular structure of the lungs. I have just relieved a patient of a polypus partially filling up the right nasal passage, and who, also, had complete occlusion of the left nasal passage from a thickened and deviated nasal septum and a hypertrophied turbinated body. Until within a year this patient had severe asthmatic attacks. Latterly these paroxysms have wholly disappeared. I attribute this fact to the falling down of the nasal polypus, and the lessened irritation by pressure of the posterior portions of the septum and turbinated bodies.

[1] The division given above is taken in great part from Elsberg (Arch. of Laryng.), and somewhat modified by myself.

Another patient is now under my care—or was a few weeks since—who had complete obstruction of both nasal passages from turbinated hypertrophies, particularly marked or excessive at the posterior portions of the lower bodies. Yet this patient, who was a great sufferer from asthma a few years ago, and when his nasal passages were relatively free, has now little or no asthma, although he cannot respire at all through the nose, and his mouth is frequently agape on this account. There are, without doubt, a great number and variety of affections, mainly neuroses, under the direct influence of morbid intra-nasal conditions; still, at the present time we should be careful not to exaggerate their importance, and whenever and wherever we find a neurosis of the respiratory organs immediately reach the conclusion that the nose occasions it. For a long time the profession has recognized a peptic asthma originating in the stomach. A cough, obstinate and paroxysmal, may also take origin in a catarrhal gastritis. A torpid and congested liver may produce a like effect, and even the spleen is not unknown to have a cough which is named "splenic." There is much truth in the observations of the past few years in regard to the predominating influence of a hyper-sensitive nose, but there is also a tendency to exaggeration in this regard, and we should be careful to exclude other efficient causes of vaso-motor coryza, cough, asthma, etc., before admitting their nasal origin and instituting severe or prolonged treatment of this organ with a view to cure the secondary affections. The nose is naturally a sensitive organ, and many times I have produced epiphora, cough, spasmodic closure of the glottis moderate in amount, and slight dyspnœa, by the mere passage of instruments or simple nasal examinations, when the result of my investigation was to show that no nasal trouble of importance existed. This is no new observation, and I am conscious that you are all familiar with it. It is probably true, as Dr. J. H. Mackenzie has shown, that areas of special morbid sensibility exist in the nose at times. That they do *not* always exist I am equally confident by reason of my own clinical researches. Are these areas of special sensibility limited, more or less narrowly, to the posterior half of the lower turbinated body, as this observer would have us believe, or are they specially assignable to the anterior part of this body, as Hack and Sommerbrodt at first stated? I cannot definitely answer this question, but would add that I am of the opinion that later observations will confirm, to some extent, at least, the fact that Hack has mildly insisted upon in his later communications, viz., that the sensibility of the nasal mucous membrane is far more general than he was prepared to accept at first, and that *areas of irritation* may occasionally be found everywhere in the nasal passages. Of course, when we read the histories of clinical cases we shall be disposed to take a one-sided view unless our reading be extensive; and when some time since I read Dr. J. H. Mackenzie's graphic report of a physician of Baltimore, in whom obstinate cough was entirely relieved by the removal of a posterior hypertrophy of a turbinated body, I had almost concluded that this distinguished observer had discovered a clinical fact to which there were few or no exceptions. Since that time, my own cases have not always corroborated this testimony, and I am forced to conclude that a medium opinion is here the correct view to hold.

Alongside of this opinion, however, comes the broad statement of Sommerbrodt, who affirms that in his one hundred and thirty-eight cases of nasal disease in which there were respiratory or other neuroses, in *all* there was marked turbinated hypertrophy. All, indeed, were treated by the galvano-cautery, and very remarkable and successful were the results achieved by him. Irrespective, however, of any nasal disease, there must at last be a special *personal susceptibility* on the part of the individual in order that the reflex phenomena be produced. Of course, the intra-nasal morbid condition may develop or accentuate this susceptibility, but the fact remains true, since we are frequent observers that *numerous* individuals suffer from nasal disease of different kinds, and yet are never affected by any reflex trouble which we can properly attribute to them. The only way in which we can avoid error is to search carefully for other cause, or causes, of these reflex neuroses, and when none are discovered, then, and then only, we should admit the nasal origin of the neurosis, and institute treatment in accordance with it.

Cocaine, according to Cartaz, is of service in making a correct diagnosis, (1) by reason of the local anæsthesia produced; (2) on account of its decongestioning power. This latter observation, which really belongs to Bosworth, must, in my opinion, be warily accepted. If cocaine be used frequently in a nose which already shows a tendency to congestion, it will finish by augmenting, rather than decreasing, this condition. And as regards its anæsthetic power, I am convinced that after a brief period, in certain cases, it loses this power to a certain degree.

At all events, it does not remain sufficient to prevent the patient from having with considerable intensity all the symptoms which combine to form vaso-motor coryza, or the one major symptom which characterizes *asthma*—viz., intense dyspnœa. In regard to treatment I will be brief. We must first, of course, treat the intra-nasal cause if it be found to exist, and must do it with appropriate means. Hack and Sommerbrodt employ the galvano-cautery exclusively, in view of their theory that in every case there is nasal hypertrophy. But, as we have seen, nasal hypertrophy does not exist always, and in such instances it may be unsuitable and injurious to use the galvano-cautery. Try, therefore, at first, milder cauterizations with nitrate of silver, chromic acid, or, what I especially favor, carbolic acid. Hunter Mackenzie has had excellent results from the use of belladonna bougies (gr. $\frac{1}{2}$—gr. $\frac{1}{6}$).

Cartaz recommends cocaine. After all, these are only palliative measures. When there is considerable hypertrophy the galvano-cautery is the best curative means. When the soft tissues are hard and fibrous the cautery loop, or suitable scissors, may be employed with good effect, as recommended by Cartaz.

REFLEX OCULAR SYMPTOMS IN NASAL AFFECTIONS.[1]

By E. GRUENING, M.D.,

NEW YORK.

In selecting this title for the paper of the evening, I desire to exclude from consideration ocular affections due to an extension of catarrhal disease of the Schneiderian membrane. Such affections are well known, and generally conceded to exist. I wish to lay before you to-night the results of some clinical observations tending to show that certain groups of ocular symptoms may be looked upon as reflex neuroses, and furthermore, that the source of the ocular disturbance may be found in certain alterations of the nasal structures. At present, the view is held by many that asthma, hemicrania, supra- and infra-orbital neuralgia are in many instances but neurotic phenomena due to reflex nasal irritation.

Voltolini demonstrated that asthma may be relieved by the removal of a nasal polypus. Hack mentions a series of two hundred and forty cases of hemicrania and eighty-seven cases of asthma cured by the galvano-caustic destruction of the hypertrophic corpora cavernosa of the nose.

A number of observers following in the wake of Hack's labors report equally favorable results. The immediate cessation of asthma, of hemicrania, of supra-orbital neuralgia, and other symptoms, as a direct consequence of the nasal treatment, argues most forcibly in favor of the reflex nature of these phenomena.

To the ophthalmologist the subject of nasal reflex is

[1] Read before the Section of Ophthalmology, November, 1885, and before the Academy of Medicine of [illegible], 1886.

of great interest. If an irritable nose may cause grave symptoms in distant parts, why should the neighboring eyes, with their direct nervous and vascular connections, be spared? Reflex ocular symptoms—for instance, lachrymation, conjunctival hyperæmia, photophobia—may be readily obtained by touching certain parts of the Schneiderian membrane with a probe, and *vice versa*; reflex nasal symptoms—for instance, sneezing—may be evoked by exposing certain irritable eyes to a bright light.

In the cases mentioned by Hack and his followers, ocular symptoms are incidentally mentioned. Lachrymation, photophobia, increased vascularity of the ocular and palpebral conjunctiva, pain and pressure in and around the eyes, fluttering scotoma, frequently co-existed with the graver symptoms and passed away with them, in consequence of the nasal treatment. Now, a certain group of ocular symptoms, namely, lachrymation, sensitiveness to ordinary light, and redness of the eyes, are presented by a considerable number of our patients, and yet the examination of their eyes reveals absolutely no anomaly. The refraction may be emmetropic, the vision normal, the conjunctiva sound, the puncta lacrymalia may be open and favorably placed, and the nasal ducts permeable.

For such cases collyria have been prescribed, cold or warm applications recommended, general hygienic measures enjoined—all without the slightest benefit to the patient. Knowing that the symptoms—lachrymation, photophobia, and increased vascularity—may be evoked at will in all eyes by mechanical irritation of the nasal mucous membrane, may we not logically infer that the continuance of such ocular symptoms may be due to the continuance of a nasal irritation? This is the *à priori* argument, and of conditional value in practical medicine. If, however, in a considerable number of pertinent cases, showing the ocular symptoms in bold relief, local and general treatment prove ineffective, and nasal treatment promptly effective, should we not then present the convincing *à posteriori* argument—"sublata causa, tollitur effectus?"

Of such cases I have observed a large number in the past two years, and I shall cite only a few of them as representatives of this class.

Case I.—H. S——, aged forty-six. He says, "My eyes have troubled me for twenty years; when I rise in the morning I feel as if I had sand in them; I cannot look at any object in ordinary light; when I converse with any one, I am obliged to put on my blue glasses in order to look at the person. Ordinary daylight and the slightest wind cause my eyes to water. My eyes are always red. I have been treated by every oculist of note in America and Europe. No one has benefited me."

Case II.—H. S——, aged thirty-four, says: "When I awake in the morning my eyes pain me. They are red and feel dry. After I have bathed my face my eyes feel much better. The transition from the sleeping into the waking state is very trying to my eyes. There is more or less watering and smarting of my eyes all day long. This condition has lasted six years. I was treated the first year, but as the treatment did not relieve me, I discontinued it."

Case III.—F. L——, aged twenty-four, a clerk, relates his case in the following manner: "In the morning my eyes are slightly glued, they feel very uncomfortable until I have washed them. They feel weak all day. I cannot bear ordinary daylight, but gaslight is still worse. When a slight wind strikes my face the eyes water. My trouble dates from early childhood. My eyes have been treated, but not improved."

Case IV.—E. H——, aged twenty-six, a draughtsman, says: "I have a constant pressure behind and around my eyes. At times only in one eye, at times in both. The upper lids feel hot and dry. My eyes water freely in the open air, but never in the house, or when I am at work."

Case V.—A. E——, aged twenty-six, salesman, makes the following statement: "My eyes feel very weak in the morning. In the street I can hardly open them. At about ten o'clock they feel better. When I attempt to read in the evening a film comes over my eyes and I cannot continue."

In the cases just mentioned the nasal alterations were slight. I found simple catarrhal affections of the Schneiderian membrane, with insignificant swelling of the corpora cavernosa, a condition so common in New York that it may be considered normal. The question will now be asked as to whether we possess any guide, in the pathological appearance of the nasal mucous membrane, pointing to the origin of the neurotic symptoms. This question must be negatively answered at present.

Why this condition should give rise to ocular symptoms in some persons, and not in others, is difficult to explain. It may be due to a special irritability of the terminal nerves of the nasal mucous membrane; it may be due to a special neurotic tendency on the part of the individual. We have a practical guide in the possible efficiency of the nasal treatment for the relief of the ocular symptoms in the use of cocaine. If in these mild cases the instillation of cocaine into the nose relieves the ocular symptoms, we may assume that a simple anti-catarrhal treatment will suffice for the cure of the affection.

But the cases which we encounter are not all of this simple nature. Very frequently we find an immense hypertrophic swelling of the corpora cavernosa of the turbinated bone. This swelling may be found at the anterior or posterior portions of the lower turbinated bones, on the lower edge of the middle turbinated bones. In other cases we have to deal with a stenosis of the nasal passages due to a variety of causes, a combination of hypertrophy of the erectile tissue, cartilaginous excrescences from, and deviations of, the septum. These are the elements with which we must cope in the successful treatment of the reflex ocular symptoms.

A few clinical observations may serve to illustrate the class of cases in which extensive pathological alterations of the nose gave rise to reflex ocular symptoms, but caused no subjective nasal trouble.

Case I.—G. J——, twenty-six years of age, is a polisher of metals. In the past six years he has been greatly troubled by the bright reflexes of metallic surfaces, so much so, that he was obliged to discontinue his work many weeks. Whenever he fixes any object in ordinary daylight, his eyes begin to water. He has been treated with astringents, electricity, internal remedies, chiefly quinine, and absolute repose in a dark room. He never derived benefit from any mode of treatment. His eyes are sound, the refraction is emmetropic, the vision normal, the conjunctiva more vascular than usual, the lachrymal apparatus apparently in good condition.

The examination of the nose shows that his mucous membrane is of a bright red color and thickened over the right lower and middle turbinated bones. In spite of this thickening the right side of the nose is spacious, and the turbinated bones are nowhere in contact with the septum.

The left side of the nose presents a stenosis, especially of the lower meatus, where a ridge of cartilage, running from the septum to the inferior turbinated bone, and coalescing with the latter, forms a bridge-like connection. Instillations of two and three per cent. solutions of nitrate of silver into the nose, and the application of nitrate of silver in substance to the thickened parts of the nasal mucous membrane, were followed by temporary aggravation of the ocular symptoms, and finally, by a slight improvement. This, however, did not satisfy the patient, as he was not yet able to work steadily. I then removed the cartilaginous ridge of the left side of the nose with a punch especially constructed for the purpose. This operation was followed by an immediate

cessation of the ocular symptoms. The patient resumed his occupation, remaining under observation six months, during which time no relapse occurred.

Case II.—Miss H——, aged sixteen, gives the following history: "When I rise in the morning my forehead and my eyes pain me very much. My eyes feel dry, and it is hard to open them to the light. When I have washed my face and taken my breakfast, my head and my eyes feel better. The slightest wind causes my eyes to water. I cannot study, because when I begin to look at my books my eyes feel brimful of water, as though they would run over if I continued. In the past two years I consulted several physicians, who prescribed eye-washes and glasses. My eyes are just as bad now as they were two years ago."

The examination of this young girl's eyes shows no anomaly.

The refraction is emmetropic, the vision normal, the conjunctiva pale. The examination of her nose yields the following result: The lower end of the right middle turbinated bone is considerably swelled. The mass obstructs the middle meatus and presses upon the septum. I anæsthetized the nasal mucous membrane with cocaine, and destroyed the swelling with the actual cautery. The relief which this patient obtained was immediate, and thus far permanent.

The frontal morning headache did not return, and the patient can use her eyes without inconvenience. The operation was performed March 5th, and the patient was feeling well on October 5th.

Case III.—H. K——, aged twenty-seven, a merchant of New York, consulted me on June 8, 1885. He related his history as follows: "My eyes began to trouble me when I was twelve years of age, and I have been under treatment fifteen years. I feel my chief annoyance in the morning, when my eyelids are very stiff and I cannot open my eyes. When I am in the open air my eyes water continually, especially in winter. In cold weather my eyes are always red, and the glare of the snow is very painful to me. I have never been able to read at night. Whenever I attempted it my eyes filled with water. I was treated with nitrate of silver in the morning, and ointment in the evening, for four years every day, then for two or three years twice a week, then once a week, then once in two weeks, then once in a month, and was finally discharged, but my eyes were as bad as before. Last year I was in Minnesota, where the cold was extreme and the snow covered the ground. My suffering was intense, and I returned to New York to consult my physician. He resorted to the former mode of treatment—a daily application of nitrate of silver to my lids. I am very much discouraged because my eyes do not improve in spite of so much treatment."

The examination of the eyes of this patient showed, as in the other cases, an emmetropic refraction and normal vision, but a decided hyperæmia of the conjunctiva, and a red and velvety appearance of the palpebral conjunctiva. The examination of the nose gave the following result: The mucous membrane covering the right lower turbinated bone was enormously thickened, and changed into a hard globular mass pressing against the septum, resting upon the floor of the nose, and obstructing the lower meatus. Under the use of cocaine the globular swelling became somewhat smaller, allowing the introduction of the wire loop of Stoerk's snare, by means of which the whole mass was removed. The distressing symptoms from which Mr. K—— had suffered so many years disappeared that very day. I saw my patient on November 5th, five months after the operation. He stated that his eyes no longer troubled him in the morning, and that he could read several hours in the evening without any discomfort.

In the past two years I examined and treated more than two hundred cases, in which I referred the ocular symptoms to nasal disease.

The treatment adopted for the cure of the nasal affection differed with the character of the pathologica changes. Thus, in simple catarrh of the nasal mucous membrane astringents were employed, while in the hypertrophic and the obstructive forms of disease the cautery, the snare, the knife, the punch were resorted to. The treatment was not uniformly successful. A number of patients, terrified by the novelty of the procedure, did not return. Many observations were therefore incomplete, but a sufficient number—a series of 150 patients—remained long enough under treatment and observation to allow the formulation of definite conclusions as to the correlation of ocular symptoms and nasal affections.

The cases here presented have the following features in common:

1. Burning and smarting sensation of the lids or of the eyes, more pronounced in the morning than in daytime.
2. Inability to fix an object in ordinary daylight.
3. Increased vascularity of the conjunctiva, and lachrymation upon slight provocation, such as a mild current of air.
4. Sound condition of the eyes and their appendages.
5. Inefficiency of the ocular and the general treatment.
6. Efficiency of the nasal treatment in spite of the absence of nasal symptoms.

THE RELATION OF REST TO THE SUCCESS OF ANTISEPTIC SURGERY, WITH REMARKS ON "LISTERISM."

By SIMON BARUCH, M.D.,

NEW YORK.

The results of antiseptic surgery in Bellevue Hospital, which were so graphically presented by one of its attending surgeons in a recent essay[1] before the New York Academy of Medicine, are extremely gratifying to American physicians, and to the advocates of "Listerism," so called, everywhere.

Scarce have these pæans of praise in behalf of antiseptic surgery passed from our hearing, when quite a different strain reaches us from one of the consulting surgeons of the same institution.[2]

While the former attributes the wonderful results to a scrupulous adherence to antiseptic treatment (introduced by Lister) previous to and during the recent operations (excepting the substitution of the spray by irrigation), the latter regards these "manipulations and devices" as "serving no other purpose than the walking, talking, and gestures of the prestidigitator. They abstract the attention and conceal the adroit manipulation by which the trick is actually performed." To the general practitioner, who must needs study for his guidance the opinions of those whose opportunities for practical observation are larger, such differences regarding the utility of important measures are extremely interesting. To sift the truth is his aim. Fortunately this may be accomplished without difficulty, on the subject under discussion, as I propose to show.

The writer is impelled to the following remarks by reading on the same day the passages quoted below. The great gulf which lies between these opinions he has endeavored to bridge over in vain, and these lines are the result of his reflections upon the subject.

Says Dr. Hamilton, an eminent American surgeon, after casting doubts upon "Mr. Lister's theory, which is far from being universally accepted," and comparing his "manipulations and devices" to those of the prestidigitator: "The prestidigitators are not deceived, but deceive their audiences; while Mr. Lister and his disciples deceive both themselves and their audiences."

Says Professor Gerhardt, the man who was chosen to

[1] The Comparative Results of Operations in Bellevue Hospital, by Stephen Smith, M.D., Medical Record, October 17, 1885.

[2] The Art of Primary Union, etc., in Large Incised Wounds, by Frank H. Hamilton, Medical Record, January 2, 1886.

wear the mantle of Traube and Frerichs: "From Lister's method a new surgery has arisen, which does not shrink from the opening of any cavity of the body, which lays the knife upon the most vital organs, which says, if thy kidney or thy pylorus offend thee, we will pluck it out and cast it away" (*Berl. klin. Wochen.*, p. 947, November 10, 1885).

Having, during a three years' service as military surgeon, and later in private practice, enjoyed considerable opportunity for observing the method of wound-dressing which he was taught twenty-five years ago, and which was in vogue up to the Listerian or antiseptic epoch, and having later, but especially during the past five years, studied the results of the antiseptic method in the New York hospitals, and to a limited extent in private practice, the writer has become a convert to the latter method without hesitation.

When I look back upon my experience in the field-hospitals at Boonsboro', Spottsylvania Court-House, and Gettysburg, and compare it with that of to-day, I rejoice that I have lived to see this happy era in surgery.

Operations (especially secondary procedures) were done with care, and anæsthesia rendered haste unnecessary; the then prevailing principles, which are enunciated so ably in Dr. Hamilton's paper, were executed as nearly as possible, especially with reference to cleanliness; water dressing was applied and the stump left at rest for two or three days. But now the work began. Each stump was exposed by removing the bandages, now soiled and saturated with decomposing fluids; sponges were plied and water was poured in order to cleanse the stump, which lay quivering and trembling within the hands of an assistant. The openings from which dangled the silk ligatures, and which were intended for drainage, were, in many instances, so closed by swelling that it was necessary to cut some of the sutures. The stump being clean, it was again bandaged and replaced. Day after day the poor patient was subjected to the same ordeal, perhaps intensified by the injection of some "disinfectant" (the word antiseptic had not yet became the surgical shibboleth) solution through the stump. This undressing and redressing was continued from day to day, sometimes several times daily, for weeks, until the patient either succumbed or the stump healed, while he was reduced to the last extreme of debility. A few cases recovered by primary union, and were displayed triumphantly as remarkable. This was substantially the practice adopted in the majority of civil and military hospitals twenty-five years ago.

To-day how changed is all this!

The chief aim of the surgeon is to make the wound as free from irritating elements as possible, and afterward to so prepare it as to render it unnecessary to repeat the dressing. Every precaution is taken to render clean and aseptic the part involved, and everything that comes in contact with it; a stream of water, rendered clean and aseptic by boiling or by certain medicinal subtances, plays from an elevated point upon every recess of the wound, gently removing clots and impurities; every bleeding vessel is tied, the ligatures being used without stint and cut short, because, being aseptic, they will not become sources of future irritation; drainage-tubes are freely introduced to lessen tension and guide the fluids outside of the wound, where the antiseptic dressing neutralizes their noxious qualities. Now the stump is placed into a dressing or "device," which provides admirably against decomposition of blood serum or pus, and in this most cleanly condition it is left to the vis medicatrix naturæ. In other words, that which all surgeons formerly attempted to accomplish by daily sponging and washing, is now far more effectively done by the antiseptic absorbent material which surrounds it. The neat Lister dressing, each of whose parts is adapted to certain ends, is now mostly replaced by large quantities of absorbent material, making a more clumsy, yet more simple and not less effective device for executing the principles of antiseptic surgery. What is the result? From every land comes the answer: A new era has arisen in surgery; wounds heal more rapidly, exhaustive suppuration is almost unknown, the ratio of mortality is wonderfully reduced by the infrequency of infective wound disease. "The surgeon should never lose a patient from the consequences of an amputation, provided shock has been overcome" (Schede).

It would be an act of supererogation to defend Listerism at this late day, and such defence would come with more force from a surgeon than from a general practitioner. But even the latter (who should ever keep abreast of the latest thought in all branches) will have neglected his duty if he cannot answer Dr. Hamilton's question: "What treatment, either ancient or modern, has presented a better record than this, furnished by Alanson (35 great amputations without a death), of Syme (20 cases without a death), of Percy (92 cases with six deaths), and of Lucas (70 cases with five deaths)?"

The statistics of modern surgery abound in "better records." I will only refer to two of these. Neuber, of Kiel, reported to the Congress of German Surgeons in April, 1880, that under his Dauerverband he treated 83 major operations, of which 60 healed under one dressing, without a single death. In his work on "Die Amputation unter dem Einfluss der antiseptischen Behandlung, Halle, 1881, Dr. M. Oberst relates 261 cases, with 14 deaths, ten of which died from collapse, one each from tetanus, anæmia, exhaustion, and habitual erysipelas.

It is a singular fact, that the chief advantage of antiseptic dressings has so often been lost sight of in discussions of this subject. To my mind, at least, it appears very probable that in the fact that, by means of the antiseptic treatment of the wound, and by the subsequent antiseptic absorbent dressings, we are enabled to place the wound at complete rest until healing is accomplished—in this fact lies the secret of much of the success of modern surgery. Gamgee has done excellent service in impressing the advantage of rest in connection with antiseptic dressings. Without rest, repair certainly cannot proceed satisfactorily. How was it possible to give the most important element free play, when the wounds were daily manipulated by undressing, sponging, syringing, and bandaging? What would be the result in a simple fracture, if the surgeon imitated the old and happily obsolete practice of wound treatment by manipulating the broken ends of bones once or oftener every day? How long a time would the healing of a simple fracture even require? Certainly many weeks and months, and in depreciated conditions it would be entirely frustrated. But surgery has long ago discovered the vital importance of *rest* in the healing of fractured bones, and the result is rapid and complete union in the large proportion of cases, when rest is fully and thoroughly given to the parts. Lister has succeeded in discovering a principle upon which the same rest may be conferred upon open wounds, whose proper cleansing formerly necessitated frequent disturbance. In the simple fracture the overlying tissues make a complete "Dauerverband" (as Esmarch calls his antiseptic absorbent dressing), which, being impenetrable, renders the site of the lesion aseptic.

Lister has enabled us to imitate this procedure by the modern antiseptic treatment of wounds. By surrounding the latter with gauze protective, cotton, tow, lint, turf, mould, wood-wool, or whatever the ingenuity of the individual surgeon may contrive in imitation of the great Lister's dressing, and in obedience to the principles first inculcated by him, we may permit large wounded surfaces, open or closed, to remain undisturbed for days and weeks. Underneath this benign protection, noxious fluids oozing from the wound become harmless; in fact the latter remains surgically clean, and the great reparative processes of nature are allowed the same full play which they enjoy in a splinted fracture. If the wound is clean and at rest, the patient is well and at rest. Those who have witnessed the frequent prostration of the pa-

tient, the rise of pulse and temperature, and nervous agitation consequent upon the "dressing" of large wounds in the pre-Listerian period, will appreciate this greatest of all boons—rest—which antiseptic surgery has conferred upon wounded men. And what shall be said of the saving of time, trouble, and anxiety to the surgeon and dresser, who were forced to spend hours upon hours in this painful work?

As the valuable paper of Dr. Hamilton, which led me to these reflections, refers chiefly to the inutility of "Listerism" in securing "primary union of large incised wounds," I may be pardoned for a quotation from Lister in relation to this point. "Under strict antiseptic treatment union by first intention has no longer the importance it used to possess. As regards the essential points of avoidance of inflammation and fever, of pain and danger, it is a matter of absolute indifference whether primary union occurs or not" (*The Lancet*, November 19 and 26, 1881). There is therefore no defence called for, upon this point, against the animadversions of the author of the paper.

The opponents of Listerism (so called) seek their chief "argument" in the fact that abdominal surgery has, in the hands of a Keith and a Tait, achieved brilliant results without antiseptics. Those who are familiar with Mr. Lister's writings would scarcely resort to this argument, inasmuch as Mr. Lister has acknowledged that he "never believed that the success of antiseptic ovariotomy should be regarded as a signal proof of the truth of the antiseptic principle." He says: "Mr. Spencer Wells and Mr. Keith achieved results which astonished the world before strict antiseptic treatment was thought of; and when, several years ago, Dr. Keith expressed to me an intention of performing ovariotomy antiseptically, I strongly dissuaded him from his purpose. Even Keith, at length adopting strict antiseptic measures, with an improved spray, for a while surpassed himself by an unbroken series of eighty successful cases" (*The Lancet*, November 19 and 26, 1881). Mr. Lister enters fully into the discussion of the relation of abdominal surgery to antiseptic treatment in the paper.

But Mr. Callender, Mr. Savory, and Mr. Bryant are also cited by the author of the paper, as having "publicly declared their non-acceptance of the doctrines of Mr. Lister." As these are general surgeons, it may be said, at least of Mr. Callender and Mr. Savory, that their practice certainly does not accord with such "public declaration."

In *The Lancet* of April 15, 1882, will be found an article headed "Modified Listerism; the late Mr. Callender's Method of Wound Dressing." This paper is written by one who styles himself "one of Mr. Callender's old dressers," and in it is urged the claim of his master *to be the greatest exponent of this system of dressing wounds* (italics mine).

In *The Medical Times and Gazette*, August 16, 1879, is an account by Mr. Savory of his method of wound-dressing. Without quoting the details, it will suffice to mention that he used carbolized catgut ligature, "then, over the course of the wound and for some distance on either side of it, I should place a layer of folded lint which has been previously well soaked in olive or almond oil containing one part in about fifty of carbolic acid; over this I should place two or more layers of dry lint, either with or without cotton wool," etc. "The principle of Lister's practice is an easily intelligible one." Again, "But the principle on which it rests is a sound one, the logical outcome of established facts." "Defined in this way, *I believe that every successful method of treating wounds will be found to conform to the antiseptic principle*" (Savory, in *The Medical Times and Gazette*, August 16, 1879).

This language does not seem to imply a renunciation of Lister's doctrine, by Mr. Savory at least.

I opine that if the mode of operative procedure and subsequent dressing of "the considerable number of equally distinguished French and German surgeons" referred to by our author as antagonistic to Listerism were investigated, it would be discovered (as in Mr. Callender's and Mr. Savory's cases), that each and every one is carrying out the principles of Lister in some "modified form," whether he irrigate with boiled, carbolized, or sublimated water; whether he ligate with aseptic silk or catgut; whether he dress with protective gauze and mackintosh, or with antiseptic cotton, tow, wood-wool or turf, or with plain carbolized oil. In formulating rules for the guidance of the average surgeon, Lister has exercised great care; by doubly barring and locking the fortress he aims to secure the patient against negligence on the part of his surgeon. The more recent "Dauerverband" of the Germans is an improvement upon the Lister dressing, inasmuch as its excessive breadth and thickness guard against possible carelessness in the application, and does not demand so much exactness of detail, while it enables the wound to rest securely without contamination from within or without.

In conclusion I would express, as a general practitioner, my gratitude to Lister for having greatly lightened my burdens, and give utterance to the hope that my confrères, who in localities distant from the medical centres perform thousands of surgical operations, will look carefully into this subject ere they permit themselves to be led back to the old method of wound-treatment.

43 East Fifty-ninth Street, January 12, 1886.

Progress of Medical Science.

Observations on the Excretion of Albumen in Nephritis.—In his graduation thesis (St. Petersburg, 1884), Dr. Korkunoff records the results of a prolonged series of observations on this important subject. Although scarcely any one topic connected with medicine has received more attention than this one, it nevertheless continues to present interesting problems that still await solution. The author directed his attention in the first place to the excretion of albumen in chronic nephritis, as influenced by conditions of rest and activity, also the time of day and night, and cognate subjects. His conclusions may be summarized as follows: 1. The absolute daily amount of albumen excreted during days of exertion is larger than that during days of rest. 2. The daily percentage of albumen in urine is also less during rest than during exertion. 3. The absolute amount of albumen in urine is larger by day than by night, during both days of exertion and those of rest. 4. The same may be said of the percentage of albumen. At the same time, it must be stated that under rest the percentage decreases by day in a considerably greater degree than by night; hence, on days of rest, the difference in the percentage between day-time and night-time is less considerable than on days of exertion. 5. A comparison between the absolute amount of albumen excreted during day-time under exertion, and that under rest, shows that in the latter case the amount is considerably less; the same may be said of albumen excreted during night. 6. Notwithstanding the fullest possible attempts to preserve identical conditions during individual observations, the excretion of albumen presents considerable variations both under rest and exertion. This circumstance, in all probability, depends upon such factors as the condition of the mind, the quality and amount of sleep, the equalization of which is impossible. Some of the other results obtained by Dr. Korkunoff may be given as follows: 1. Under exertion, the amount of urine is larger by night than by day; under rest, the difference is effaced, or even inverted. 2. During exertion the daily amount of urine is, as a rule, larger than during rest. On the other hand, when we compare the amount of urine excreted with the amount of water ingested by the patient, we find that during exertion, while the patient drinks more water, he excretes relatively smaller amounts

of urine; on the contrary, under rest, the amount of urine is larger than the amount of drink. In other words, exertion brings about an increase in the loss of water by the skin and lungs, while during rest the largest part of the water taken is filtered through the kidneys. 3. During exertion, the specific gravity of urine is higher by day-time than by night, the difference being less marked and sometimes even reversed under the influence of rest. The second part of the author's work describes the outcome of his observations on the excretion of albumen in chronic nephritic patients under the influence of the sudorific treatment by warm baths, with subsequent packing in blankets. The patients were put in bed three days before the observations, and remained there during the whole time of the latter. Each observation lasted eight days, for four of which the patient remained without any treatment, and for the next four took daily two baths of 101.75° F. each of half an hour's duration. From this series of observations, Dr. Korkunoff draws the following conclusions: 1. The absolute daily amount of albumen in urine in bath-days is mostly smaller than in days without baths. 2. The per cent. amount of albumen also lessens under the influence of baths. 3. The weight of the body invariably decreases, the decrease being proportionate to the amount of dropsy present; that is, the more dropsical the patient is, the more considerable is the loss in his weight. 4. The amount of urine invariably lessens, but the specific gravity of the latter increases, in spite of the fact that the amount of water ingested by the patient during the diaphoretic treatment is always larger. 5. The loss of water by the skin and lungs is considerably increased by the sudorific treatment. In all the cases dropsy rapidly disappeared or greatly diminished under the use of baths. From the fact that the absolute and per cent. amount of albumen is diminished by the diaphoretic treatment, the author deduces the practical corollary that warm baths act not only symptomatically, but also produce a favorable influence on the morbid process in the kidneys; for, by their diminishing the excretion of albumen, they stop the progress of general exhaustion of the patient, and relieve the irritation caused to the kidneys by the egress of albumen.

Charcoal Enemata in Typhoid Fever.—Dr. Duval writes in *l'Abeille Médicale* of December 21, 1885, calling attention to the value of rectal injections of charcoal in the treatment of typhoid fever. He gives small enemata of simple water, containing a tablespoonful of vegetable charcoal, two or three times in the twenty-four hours, and finds that by this means he is able to cure the meteorism, and also to destroy the fetid odor of the stools. At the same time there is usually a marked improvement in the general symptoms, thus seeming to prove that no small part of the danger of this disease is due to the resorption of septic material contained in the rectum.

Perforative Peritonitis.—Dr. Ebstein sums up the results of his observations on peritonitis from perforation as follows: 1. As in acute diffuse peritonitis, so also in peritonitis following perforation of the stomach or intestine from ulceration or other cause, there may be contraction of the abdominal muscles; this may be very intense, and its duration may vary. Death may occur while it is present. As a rule, the contraction gives way to more or less swelling of the abdomen, with or without tension of the abdominal muscles. 2. When contraction of the abdominal muscles is present, perforative peritonitis may be suspected: *a*, if symptoms of acute diffuse peritonitis be present; *b*, if liver-dulness, which was known to be present before the symptoms set in, disappear partly or completely, and if there be a doughy condition of the epigastrium, with a distinctly tympanitic, generally high, percussion-sound. 3. The last-named symptoms, however, lose much of their value when the abdomen is much distended, as great distention of the bowels may produce perfectly analogous signs. The statement of the patient that he has felt as if something were torn in his belly has a certain diagnostic value. Dr. Ebstein disapproves of moving or shaking the patient for the purpose of diagnosis, as being dangerous, and of doubtful value. 4. Persistence of liver-dulness in perforation of the stomach or bowel into the peritoneal cavity indicates, provided the liver be not fixed in its position, that the peritoneal cavity contains fluid and not air, or that perforation has taken place a short time before or after death. 5. In some cases of peritonitis from perforation of the stomach, only the contents of the stomach escape into the peritoneum, but no air. The escape of fluid ingesta is followed by very acute peritonitis; if this do not occur, the perforation has taken place after, or a very short time before, death. 6. The absence of vomiting when peritonitis is present, and its arrest when diffuse acute peritonitis has set in and the patient remains conscious, indicates either that the peritonitis has been caused by perforation of the stomach, or that perforation has supervened on diffuse peritonitis. Vomiting is absent where perforation takes place into the general peritoneal cavity; and the same may be the case when the opening leads into the omental sac. Vomiting may occur in peritonitis from perforation of the stomach, or may recur after cessation, if the opening become closed by adhesions to the neighboring parts.—*Zeitschrift für klinische Medicin.*

Quintuple Pregnancy.—Dr. Polyakoff reports the following remarkable case (*Meditsinskoe Obozpénye*, No. 10, 1885): A robust peasant woman, twenty-seven years of age, of Syarai, Russia, married nine years, became pregnant for the seventh time in June. During the latter part of her pregnancy the abdomen was seen to be very large, and the patient suffered from dyspnœa and great weakness. Labor began on March 1st, and five female children were born one after the other at short intervals, three presenting by the occiput and two by the feet. Each fœtus had a sac to itself with a separate amnion, but there was one chorion common to all. The first fœtus, which was deformed, was born dead, the others lived for a few minutes subsequent to birth. There was one placenta, weighing about one pound and a half, and to its edge the umbilical cords were attached. Four of the fœtuses were regularly formed, but the first one born was microcephalic, and had less than the ordinary number of fingers and toes. The umbilical cord attached to this fœtus had one artery and one vein, but the others had each three vessels.

Poisoning from the Fumes of Fulminate of Mercury.—MM. Marie and Conde report four cases of this sort occurring in persons employed in shooting galleries. In some there was simply stomatitis, in others there were muscular tremors in addition. The individuals passed all their time in the galleries, and the cases of poisoning occurred in the winter, when the doors and windows were kept closed. The symptoms made their appearance very soon after a new style of cartridge, in which fulminate of mercury was used, had been adopted. The authors believe that the poisoning was due to the fumes arising from the combustion of the fulminate of mercury in the percussion caps.—*L'Union Médicale*, December 19, 1885.

Cerebro-spinal Meningitis without Symptoms.—A case is reported by Professor Lepidi of a man seventy years old, a hard drinker, in whom a diagnosis of pneumonia was made, but in whom, after death, there were found also the lesions of cerebro-spinal meningitis. With the exception of a little headache and delirium, not uncommon in hard drinkers suffering from pneumonia, there had been no symptoms of cerebro-spinal inflammation. In the meningeal exudations were found micrococci similar to those of pneumonia.—*Gazzetta degli Ospitali*, December 13, 1885.

A "NEW THEORY OF INFLAMMATION."

THE gross phenomena of inflammation are comparatively simple and easily observed. The four cardinal symptoms noted by Celsus—*rubor*, *tumor*, *dolor*, *color*—have been accepted by all later observers, and modern pathology only adds a possible fifth—the *functio læsa*, *i.e.*, arrest of function in the inflamed part. Histology and chemistry have shown that these grosser disturbances are caused by certain vascular and textural changes, such as dilatation of blood-vessels and increased porosity of their walls, exudation of the plasmatic constituents of the blood and passage out from the vessels of white and red blood-cells. Recent studies also show that the inflammatory process is a destructive and depressive one so far as the tissues are concerned; that it does not irritate and kindle into increased activity the protoplasm of the cells, but, rather, the reverse.

Still further, it is known that inflammation is always started by some irritant or injurious influence acting either upon the blood-vessels or the surrounding tissue, or both.

But pathologists are not yet satisfied simply with having learned the natural history of the inflammatory process. We have had, therefore, at different times, various "theories of inflammation;" that is to say, attempts to formulate a law governing all the phenomena of inflammation. The neuroparalytic and neurospastic theories of Henle and Stilling, Hoffmann, Budge, and others, have long passed away and been discarded as insufficient. The "inflammatory stimulus" theory of Virchow, and the theories of tissue attraction suggested by Paget, Simon, and others, have also been shown to be incompetent. Of late years, owing mainly to the labors of Cohnheim and his pupils, what may be termed the "vascular theory" of inflammation has very largely prevailed. According to this, the inflammatory phenomena are due fundamentally to some injurious influence acting on the vessel or its walls. This influence may come from without, as in trauma, or from within, as in infected blood. In any event, the vessel dilates, its walls become more porous, blood-cells pass out, and plasma exudes.

Changes in the tissues occur either before, during, or after the vascular phenomena, but these changes are destructive and degenerative, and do not cause cell multiplication. The pus-cells present come from the blood.

Despite much opposition, the vascular theory of inflammation still maintains itself as the most satisfactory one yet offered.

Recently a young surgeon of Leipsic, Dr. Landerer, has propounded another theory of inflammation, which he calls the "mechanical" (*Volkmann's Sammlung Klinischer Vorträge*, No. 259).

Dr. Landerer calls attention to the fact that the pressure of the blood in the capillaries is so great that unless there were a supporting pressure from the tissues and fluids outside they would dilate and be unable to retain their contents. The intra-vascular pressure in the capillaries is estimated by Von Kries to be at least equal to twenty millimetres of mercury, or two hundred and fifty millimetres of water. The extra-vascular pressure, on the other hand, is estimated by Landerer to average about one hundred millimetres of water. The elastic cushion of tissues about the capillaries, therefore, exerts a constant supporting pressure equal to about one-third of the expanding intra-vascular pressure. Now, in inflammation it is believed that these surrounding tissues are injured, lose their elasticity, the capillaries receive less support; hence they dilate and blood surges into the affected part. Landerer does not deny the influence of injury to the vessel-wall or the potency of vascular factors in the production of inflammation.

In œdema the tissues are relaxed, but are much less affected than in inflammation. In arterial hyperæmia and congestion of nervous origin there is a paralysis of the arterioles while the tissue elasticity is not affected. Hyperæmia from irritants and heat is like the first stage of an inflammation.

Dr. Landerer considers inflammation a conservative and protective process, designed to relieve the organism of irritable and destructive agencies acting upon it. Inflammation, with him, is a reparatory process, and it is not wise to combat it. He advises the use of warm applications, and rarely of cold, except as an anæsthetic.

We believe that Landerer's observations should be accepted as adding something to our knowledge of the phenomena of inflammation. If correct, they throw new light upon its mechanism. The few pertinent facts which he appears to have established, however, are not sufficient to form the basis of a new theory of inflammation.

THE PHENIC-ACID TREATMENT OF PHTHISIS.

IN the modern treatment of phthisis there is about an equal activity among those who are urging antiseptic and those who are urging supporting medication. Pulmonary injections, inhalations, forced feeding, rectal feeding, dry or compressed, and medicated air are among the measures that are receiving attention.

M. le Dr. Filleau (*Journ. de Médecine de Paris*) believes phthisis to be a parasitic disease, and one to be combated by anti-parasitic remedies. Of these, the most potent against the bacillus and least injurious to the human system is pure carbolic acid. This he does not think should be applied topically, but rather should be given internally. Carbolic acid, he says, is largely excreted by the lungs, and in its passage out the parasite's activity is suppressed and the healing process promoted.

He recommends that the acid be administered hypo-

dermically, and in a considerable experience has never seen any harmful or unpleasant local symptoms develop. His formula is:

℞ Aquæ destillat..... q.s.
Glycerin..... q. s.
Acid. phenic. crystalliz..... 1.00

M. Sig.—Of this, one hundred drops (about gr. ij. of the acid) are injected hypodermically daily, or every other day.

Dr. Filleau states that as much as two grammes of phenic acid can be administered daily, a dose which would require a very large number of injections. Four cases are reported illustrating the efficacy of this phenic-acid treatment of phthisis. The conclusions reached are: 1st, that carbolic acid is the only anti-parasitic as yet known which can be administered subcutaneously in large doses during an indefinite time without causing accidents; 2d, that under the influence of this medication the general state of the patient is promptly ameliorated, the local state is at the same time advantageously modified; 3d, that the tolerance and harmlessness of the drug thus administered are demonstrated (symptoms of carbolic-acid poisoning may appear, but they always come gradually and are quickly relieved by stopping the medicine for a time); 4th, that the treatment must be continued for a long time.

A NEW EXPECTORANT AND SUBSTITUTE FOR SENEGA.

Senega is an old remedy, and one whose virtues have been well established by clinical experience. It, beyond any doubt, has the power of rendering thick mucus in the bronchial tract thinner, and thus more easily expectorated. It is indicated, therefore, in the second stage of acute bronchitis, in emphysema, and in chronic bronchial catarrhs, and bronchial blennorrhœa. It has been given, also, in the resolving stage of acute pneumonia. In these conditions Stokes placed senega at the head of the expectorants. Its use is contra-indicated in phthisis, in febrile conditions, and when the digestion is disordered.

We are told, however, by Professor Rudolph Kobert, of Dorpat, in an article recently published in *The Practitioner*, that of late years the commercial specimens of Polygala senega have been of very unequal quality. The active principles of senega reside in a substance known as polygalic acid, which is in reality a mixture of two other substances both glucosides. The quantity of these glucosides in senega-root is very insignificant, and thus it comes about that one only gets a satisfactory effect when the infusion or decoction is very strong, *e.g.*, 10 or 15 parts in 200 of water. For all these reasons it appears that senega has come to be very little prescribed, and its employment is even entirely abandoned by some physicians.

Professor Kobert announces that he has found that the same active principles which occur in senega are present in another drug that costs only one-fifth as much, viz., the bark of quillaia saponaria. Kobert calls the two glucosides that are usually known as polygalic acid "quillaic acid" and "sapotoxine." He states that it has been found, by clinical investigations in Halle, Strassburg, Freiburg, and elsewhere, that the administration of senega can be very efficiently replaced by that of quillaia.

The therapeutic results, he says, hitherto obtained may be expressed as follows: When expectoration is difficult from the tenacity of the mucus, it is facilitated through the latter being rendered thinner and more copious; at the same time the stimulus to expectorate is increased. It naturally follows that this remedy is not suitable for every case, and that it must not be employed when the urgency to cough and the raw feeling in the throat gets too acute. Vomiting and diarrhœa occur much seldomer than after the use of senega. Any aromatic or simple bitter may be used with it as a flavoring agent. The drug itself contains a large quantity of a sweet carbohydrate, and consequently can be employed in the case of poor persons quite well without any corrective, which is, of course, not the case with senega. The remedy is contra-indicated in cases of ulceration in the throat, or in the gastro-intestinal disturbances, since it is too energetic an irritant for such.

REFLEX NEUROSES FROM NASAL DISEASE.

Since the appearance of the monograph of Dr. W. Hack, of Freiburg, on the operative, radical treatment of migraine, asthma, hay-fever, and numerous other related manifestations, which was the subject of an editorial in a recent number of The Medical Record, German literature especially has abounded in confirmatory clinical evidence of the views promulgated by this author.

Hack, Fraenkel, Sommerbrodt, and others, have demonstrated by clinical observations that many hitherto obscure neuroses display a relation to certain conditions mostly found in the mucous covering of the inferior turbinated bone, anteriorly, which enabled them to relieve or cure the former by removing the latter. Among the neuroses referred to, nightmare, asthma, cough, migraine, supraorbital neuralgia, attack of giddiness, epileptiform attacks, hay-fever are the most prominent in the clinical histories furnished by these authors.

The condition referred to as existing in the nasal fossa is not the hyperplastic or inflammatory thickening connected with rhinitis and nasal catarrh, but a puffed and erectile state of the covering of the anterior portion of the inferior turbinated bone or bones due to distention of the cavernous spaces underlying it. The differential diagnosis is not difficult, inasmuch as the latter condition may be recognized by the yielding of the puffed mucous membrane to the gentle pressure of a probe very much as a moderately filled cyst would do, while in the former (hyperplastic) condition pressure will not produce this effect. The degree of swelling varies greatly: it may touch the septum or not, it may yield entirely or partly to pressure of a probe, but it always returns when the probe is removed. This peculiar erectile character is pathognomonic, and may be discovered by any intelligent practitioner who will take pains to look for it.

We refer to the subject again with the view of calling attention to the recent discussion in the Academy of Medicine, of which a report will be found in our columns to-day. It is to be regretted that the diagnosis of these nasal complications and etiological factors was not dwelt upon by the readers, because this is a subject of

great importance to the general practitioner. Indeed, as has been emphasized by one of the speakers, who alone described this peculiar nasal affection, this question is of far greater import to the general practitioner than to the specialist. When a man suffers from migraine, asthma, or neuralgia he will not apply to the specialist but to his family physician for relief. If the latter be not alert and well-informed on the subject of reflex neuroses from nasal troubles he may treat many such cases in vain. If, however, he will in every obstinate case inspect the nasal fossa, he may confer a lasting boon upon the patient by discovering an obscure cause, and either himself removing it or referring the case to a specialist.

It has been found that frequently the nasal symptoms are not well pronounced, hence the necessity of "interrogating" the nose in every obstinate case. We commend the study of the subject to general practitioners and neurologists.

News of the Week.

Ligature of Femoral Artery under Cocaine.—Dr. Joseph W. Howe ligated the femoral artery for popliteal aneurism, under cocaine, at St. Francis' Hospital, New York, last Tuesday.

The Meeting of the Medical Society of the State of New York.—It is expected that the meeting of the State Society, which will be held in Albany, commencing Tuesday next, at 11 A.M., will be largely attended. More papers have been promised than ever before, and the programme, as arranged by the President, Dr. Vanderveer, and the Business Committee, presents unusual attractions. The sessions will probably be continued through Thursday. Delegates and members desiring reduced rates should communicate with Dr. Manlius Smith, the Secretary, at Syracuse, N. Y.

The Purity of Milk.—The Court of Appeals declares the law constitutional which fixes a standard of purity for milk. The Court of Sessions of Albany convicted the defendant Arthur Cipperly of misdemeanor, charging him with selling adulterated milk, in violation of Chapter 202 of the Laws of 1884. It was selected as a test case, and the decision disposes of the whole subject at once. The General Term had reversed the judgment of the Court of Sessions, and now the Court of Appeals reverses the decision of the General Term and affirms the decision of the Court of Sessions.

A Long Range Quarrel.—The *Therapeutic Gazette*, of Detroit, accused the editor of the Transactions of the *Sei I Kwai*, of Tokio, Japan, of plagiarizing one of the former's articles. The gentleman of the *Sei I Kwai* retorts by asserting that the article in question appeared in his journal four months before it did in the *Gazette*, and gives us "the deadly parallel columns" in both Japanese and English to support his assertion.

New York Post-Graduate Medical School.—Dr. Henry J. Garrigues has been elected Professor of Obstetrics; Dr. C. C. Rice, Instructor in Diseases of the Nose and Throat; Dr. F. B. Carpenter, Instructor in Diseases of the Skin.

The New England Hospital for Women and Children has received a bequest of $10,000 by the will of the late Isaac D. Farnsworth.

The Man of the Day.—The Eden Musée, a waxworks museum of this city, announces: "Monsieur Pasteur performing his operation upon one of the Newark children!"

"What Mrs. Grundy Says: 'That the doctor who writes a book gives himself away, by showing that his time is not disturbed by patients.'"—*Evening Express.*

The Way They Do It.—The trade in homœopathy is becoming systematized. We have received the announcements of a new up-town homœopath, which furnish a good illustration of how they do it. The announcements in question were mailed to the clergymen, and to the neighbors, friends, and to the business men of the vicinity. First is a card, with name, address, etc., upon it; next is a neatly printed note signed by several homœopaths of neighboring cities, and stating that Dr. X. is a skilful homœopath, and most "solid" in the faith; last comes a folded card, vest-pocket size, containing a brief popular essay on pure homœopathy and its advantages. Address and office hours are conspicuously displayed. The whole makes a very creditable typographical and literary display. No doubt it will bring in many patients.

The significance of it all is that certain men believe that they can succeed by announcing, not that they are physicians, but that they are homœopaths. They trade upon the name as quacks do upon their specially potent pills.

Such men are to be treated like any other quacks. But all men using homœopathy do not resort to these practices. Hence the mistake of damning the whole for the sins of part and thus creating a sentiment of sympathy which does so much to keep homœopathy as a distinct form of dogmatic medium alive. The Homœopathic County Society should discipline this man.

Dr. Jonathan Cass, of this city, died on January 22d, at the age of sixty-one years. He was graduated from the Albany Medical School in 1855–56, and commenced the practice of medicine at Great Barrington, Mass. When the war broke out he entered the army as surgeon, and served four years. In 1870 he came to New York, where he had lived ever since.

Death of Dr. McAllister, of Marion, Ala.—Dr. W. T. McAllister, a prominent practitioner of Marion, Ala., died of phthisis, January 13, 1886, aged fifty-six years and eight months.

German Physicians at St. Petersburg.—The profession at St. Petersburg has been somewhat excited by some selections which have recently been made to some rather coveted hospital appointments. The question of nationality has been rather unpleasantly obtruded, the "thorough Russians" complaining that they are being elbowed out by Germans, and their opponents retorting that there are many hospital superintendents whose names are German, and who may be of German descent, and even speak German at home, but they are all bound to be Russians.

Reviews and Notices.

CLIMATOLOGY AND MINERAL WATERS OF THE UNITED STATES. By A. N. BELL, A.M., M.D., Editor of *The Sanitarian*, Member of the American Medical Association, American Public Health Association, American Climatological Association, Medical Society of the State of New York, Kings County Medical Society, N. Y., Honorary Member of the Connecticut Medical Society, Corresponding Member of the Epidemiological Society of London, formerly Passed Assistant Surgeon United States Navy, etc. New York: William Wood & Co. 1885.

THIS book forms the October number of Wood's Library. It contains a vast amount of statistical information concerning the climate of different portions of our country, and also gives the composition of all the mineral spring waters used in medicine. It is a source of astonishment, to one who reads this work, to see the great variety of climate which the citizens of this republic enjoy or suffer under, and he cannot but wonder that it should ever be thought necessary to send consumptives or other patients to Europe, when precisely similar meteorological conditions are to be found in our own country. The subject of climatology in general, than which nothing is regarded by the ordinary reader as drier, is here presented in such a shape as to be almost interesting.

DIAGNOSIS OF DISEASES OF THE BRAIN AND OF THE SPINAL CORD. By W. R. GOWERS, M.D., F.R.C.P., Assistant Professor of Clinical Medicine in University College, Physician to University College Hospital, and to the National Hospital for the Paralyzed and Epileptic. New York: William Wood & Co. 1885.

THIS volume contains the substance of the lectures delivered by the author at University College Hospital, London. The first three lectures of Part I. are devoted to a consideration of the anatomy of the brain. Then follows a review of the symptoms of cerebral disease arranged under the different headings of motor and sensory symptoms; those connected with the organs of special sense, and the affections of speech; and in the concluding lectures the diagnosis of the diseases of the brain is treated of at length. In Part II., which is much shorter, the same general order of subjects is followed, although the division of the work into separate lectures is not adhered to. Illustrations are introduced wherever they serve to elucidate the text. The book is one that will well repay perusal, and no one who reads it can fail to learn something. It forms the concluding (December) number of Wood's Library for 1885.

VENEREAL MEMORANDA. A Manual for the Student and Practitioner. By P. A. MORROW, A.M., M.D., Clinical Professor of Venereal Diseases in the University of the City of New York; Surgeon to Charity Hospital; Attending Surgeon to the Bellevue Hospital Out-door Relief, Department of Skin Diseases, etc. New York: William Wood & Co. 1885.

THIS little volume, one of Wood's Pocket Manuals, contains a large amount of practical information in very condensed form. It is not a good work for a student who is commencing his studies, but for one who has finished his preparatory course and is making a hasty review for examination, it will be of the greatest service. It is an excellent guide also for the general practitioner who has no time to study voluminous treatises, but who may wish to refer to some special point in the diagnosis or treatment of one of the venereal diseases. He will find here just what he wants, and will find it expressed clearly and well.

THE DOCTOR AHEAD.—"If I were so unlucky," said an officer, "as to have a stupid son, I would certainly make him a doctor." "Well," said a doctor, who was in the company, "you think differently, sir, from your father."

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, January 25, 1886.

DANIEL LEWIS, M.D., PRESIDENT, IN THE CHAIR.

Dr. ROBERT ABBE read a paper entitled

THE ADVANTAGES OF THE OPEN METHOD OF RADICAL CURE OF HERNIA.

The major cutting operation for the radical cure of hernia is as old as the history of surgery, but some textbooks have mentioned it only to condemn, and have echoed the aphorism of Petit, that "nothing justifies operation on a hernia, except strangulation of its contents."

From the date of the Berlin Congress, in 1879, when Czerny reported six cases cured by the open operation under antiseptics, there have been scores of names enrolled in many countries sanctioning the method. In this country, however, the operation has not even yet been practised widely. It was opportune, therefore, to look into the value of the open method and its advantages.

The favorite course pursued in the "open method" of operating consists of cutting down to the sac, while it is distended with gut, stripping it clean of all cellular layers and the elements of the spermatic cord, so that the sac and its contents are lifted out of the scrotum and the fingers can be slipped along the neck of the sac into the ring; then reducing the hernia and carefully slitting open the sac, inspect its interior, sweeping the finger around the abdomen, within the canal, to discover adherent bands; then pass a heavy catgut ligature around the neck of the sac as high as within the ring, if possible, tie the sac off, and cut away below the ligature. After this has been done, approximate the pillars of the ring tightly, leaving only room for the exit of the spermatic cord; most surgeons use heavy catgut for this.

These details vary with circumstances. If the bowel is adherent to the lining of the sac by recent adhesions, it may be stripped off; if old adhesions hold it, the sac is to be cut away nearly to the intestine, and its edges stitched together. The Liverpool surgeons use silver wire instead of catgut for closing the pillars of the ring. Keetley, of London, after exposing all the parts, injects into the cellular tissue of the canal, and rubs into the loose cellular planes, the Heaton fluid, and then brings the pillars of the ring together over that with catgut.

Dr. Abbe then gave briefly the notes of *twenty-one* cases which had been under his personal care. Of these *sixteen* were operated on when not strangulated, and five when seriously so. In each, however, an attempt was made to secure a radical cure by the latest methods.

The results admitted of the following comments: *First*, is the open operation a safe one? and *second*, does it effect a radical cure?

If we accept the statistics of the Liverpool surgeons, with 125 successive cases without a death, and four-fifths of them successful in the result, it must be admitted that it is safe; but no one else has obtained such results.

The proportion of fatal results following the open method in the hands of the best operators makes it about one in eight. This means, probably, that only the worst and most dangerous cases have as yet been induced to submit to the operation, and serious complications are here encountered, such as adherent intestine, feeble patients with fatty hearts, etc. Hemorrhage has happened to the best operators everywhere. An omental pedicle is specially liable to accident, because it is a mass of fat which wastes quickly, and allows the inner folds to slip out from the grasp of the ligature. This can be overcome. Septic peritonitis, erysipelas, and hospitalism have been driven to the wall by clean antiseptic work.

As regards suppuration, Dr. Abbe had frequently been disappointed in finding hernial wounds suppurating when

heavy sutures had been applied to the ring, especially silver-wire and silk. But on the whole, although we dislike to have it occur, he was strongly of the opinion that union by granulation sealed the canal and matted together the ring tissues in a much more secure way than primary union did, and that return of the rupture was less likely to occur. In any case, however, after the operation the patient should support the part from without for many weeks, perhaps for months, to insure permanent relief.

As regards return of the hernia, he thought it extremely probable that in most cases there would be partial recurrence within one or two years; much less likely to follow femoral than inguinal hernia.

This, however, is no sign of failure of the operation, for it almost invariably restores the patient to working power, and from complete invalidism to comparative health. He had yet to see a patient who was not loud in praise of what had been afforded by the operation. His belief was that in simpler cases of small but annoying herniæ, where the patient could be kept on his back for a month and watched afterward, the open operation had a large field of usefulness; while to the sufferers from incarcerated omental masses and ever-recurring intestinal herniæ it was an undoubted boon. He also agreed with Keetley in the opinion that it was safer and more sure to cure in femoral hernia, especially when there is adherent omentum; and it is in these cases especially that the danger of strangulation is greater (eight to one) than in the inguinal hernia.

Dr. A. G. Gerster said he could agree with almost all that had been stated by the author of the paper.

His experience included twenty-five cases, in which he had, in addition to herniotomy, performed the operation for radical cure. In eight cases he had performed the operation for radical cure where there was no strangulation, but the symptoms demanded that something should be done to improve the condition of the patient, if possible. In the cases in which the abdominal rings were not very large the best results had been obtained. Under antiseptic precautions he regarded the operation as a safe one. So far as results were concerned, the appellation "radical cure" was a misnomer, as relapse occurred unless a truss was worn—although a very light truss might be all that would be required. He regarded the cicatricial plug as more efficient than primary adhesion.

Dr. R. F. Weir had operated in eight cases unaccompanied with strangulation. For large irreducible herniæ he regarded the open operation as a good one; also for reducible herniæ which had existed so long that practically the rings are one, and where Heaton's method cannot be applied or has failed. In two or three of his cases suppuration and constitutional disturbance were considerable, but they terminated favorably and without peritonitis. Dr. Weir, however, had not lost faith in Heaton's method, and while he could obtain success in from one-third to one-half of the proper cases by its use, he should be unwilling to extend the cutting operation to these cases.

Dr. O. A. White exhibited an instrument which he devised about the year 1858, and which he had used successfully in a great many cases for the cure of hernia. It was a modification of Wurtzer's plug and transfixion pin, and had *two* needles, and weighed only half an ounce. The scrotal sac is inverted, the needles plunged through, and the whole secured in position by a ligature thrown around two side clamps; it is allowed to remain in position about four days.

Dr. Abbe, in closing the discussion, said that history had not recorded any harm done by transfixion-needles, and yet it was difficult, when the parts were exposed by operation, to see how they could be used safely. He thought the open method best, because the operator could see what he had to deal with. He thought that the tendency would be to change the opinion now held largely by surgeons, if it should be found that further statistics sustained the "open method" of treatment.

Dr. P. A. Morrow then read a paper on

THE DIAGNOSIS OF SMALL-POX,

in which he gave the features of a typical case of small-pox, and its differential diagnosis from measles, varicella, syphilis, papular eczema, lichen febrilis (classed as eczema), sudamina, pemphigus, herpes, erythema and urticaria (papular forms), and acne (produced by drugs and otherwise).

The paper closed with remarks on vaccination and reference to small-pox not necessarily extinguishing the susceptibility to vaccination.

Dr. McLaury referred to a paper recently read by Dr. P. C. Cole, in which the writer stated that variola frequently occurred the second time, and that it was as necessary to be vaccinated after having small-pox as before; these statements were based upon observations made in the army.

Dr. Sell mentioned a case in which Hebra and Kaposi mistook syphilis for small-pox.

Dr. Mittendorf spoke of a case where the diagnosis of small-pox was made, the patient sent to the Island, but which turned out to be a case of syphilis; and the patient had double iritis develop while in the hospital which terminated in total loss of vision in the right, and nearly complete loss of sight in the left eye.

Dr. Vineberg spoke of the prodromal rashes, occurring mostly on the inside of the thighs, as characteristic of small-pox.

Dr. A. B. Judson mentioned a case in which the diagnosis of small-pox was made, but which proved to be a case of acne in which relapsing fever occurred.

Dr. Abbe referred to the differential diagnosis of small-pox and varicella, and said that in a special case Dr. Taylor, of the Health Department, based his diagnosis on the fact that in varicella the vesicle is cuticular largely, and that the vesicle of variola springs from the deeper tissues.

Dr. Morrow said that the prodromal rashes were very uncertain, being absent entirely in some epidemics. With regard to the point mentioned by Dr. Abbe, he hardly thought that any one could safely discriminate between varicella and small-pox by simply inspecting with reference to the superficial and deep-seated character of the vesicles.

Under the head of

NEW BUSINESS,

Dr. P. A. Morrow was elected delegate to the Medical Society of the State of New York, to fill the vacancy caused by the resignation of Dr. W. T. Alexander.

Dr. G. M. Smith gave a brief outline of the history of the action of the Society and the Academy of Medicine concerning contagious eye diseases, and offered the following preamble and resolutions, which were adopted.

Whereas, Contagious ophthalmic disorders in asylums and residential schools seem to have become almost permanently attached to many of these institutions, though at times prevailing to a greater extent than at others;

Resolved, That the Medical Society of the County of New York deems it necessary to invoke legislative action in order to eliminate the causes of disease which are temporarily, and often permanently, injuring the welfare of the occupants of such Asylums.

Resolved, That this Society endorses and recommends to the Legislature of the State of New York, the law drafted under the auspices of a Committee of the New York Academy of Medicine, and subsequently approved by the Academy—the law being denominated "An Act for the Better Preservation of the Health of Children in Institutions."

The President announced that the initial steps had been taken for the publication of a Register of the medical profession of the county, and that it would probably be ready for distribution early in May next.

The Society then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 23, 1885.

JOHN A. WYETH, M.D., PRESIDENT, IN THE CHAIR.

MULTIPLE STRICTURE OF THE URETHRA—PERINEAL ABSCESS—ABSCESS OF THE KIDNEY.

DR. WACKERHAGEN presented a male genito-urinary apparatus which showed laceration of the mucous membrane of the urethra, a false passage, and between the urethral laceration and the prostate behind an abscess cavity, two and a quarter inches wide, two inches long, and containing a large ragged slough. The cavity of the bladder was about the same size as that of the abscess. The ureters were slightly dilated. Pus had been traced as high as the right renal pelvis; the left kidney contained abscess cavities. The specimens were removed from the body of a Scotchman, forty-six years of age, who twenty years ago suffered from gonorrhœa which was followed by no noticeable sequelæ. A few months before death there was increased frequency of micturition. Examination of the urine was negative. Last July he had a perineal abscess, which, as near as could be learned, began its formation three months previously, when he noticed a slight perineal swelling. About the middle of November last Dr. Wackerhagen saw the patient in consultation, when there was almost continuous dribbling of ammoniacal urine through the perineal sinus. There was phimosis, three urethral strictures, and a contracted meatus urinarius. He advised circumcision and internal urethrotomy, which were performed. The general condition of the patient for a time improved, and he was occasionally sounded afterward for the purpose of keeping the divided strictures dilated. Nine days after the internal urethrotomy external perineal urethrotomy was performed. The patient died eight days after the operation. His temperature was normal throughout his entire sickness, until within a few days before his death, when, without chills, the temperature rose, 102° F. being the highest.

THE PRESIDENT said the case was especially interesting to him as he at present had one of urinary fistula under observation, with an abscess in front of the rectum, giving identically the history related by Dr. Wackerhagen, except that the patient has had chills. The urine is now being discharged through an opening in front of the scrotum, and pus posteriorly. The patient is also emaciated to an extreme degree.

DR. WACKERHAGEN said his patient was so extremely reticent that he probably would not have said anything about the chills if he had had any.

DR. L. EMMETT HOLT presented specimens from two cases that were specially interesting in point of contrast. One patient during life had shown many symptoms of tubercular meningitis, but the organs showed at the autopsy no evidence of tubercle. The second case was one of latent tuberculosis, the patient being apparently in good health until three days before death. Both patients were observed in the New York Infant Asylum, and acknowledgments were made to Dr. Thelberg, the resident physician, for particulars in the histories.

MENINGITIS (?)—CROUPOUS DYSENTERY.

CASE I.—N. B——, male, aged fifteen months, a rather delicate child, began to show marked symptoms on November 7th. The child had been wet-nursed until a few days before. Nothing was known of the family history. Had made no attempt to walk, had only four teeth, the fontanelle was widely open, and other signs of rachitis were fairly marked. He was taken with a temperature of 102° F., and for six days it ranged between 101° F. and 104° F., falling only once below 100° F. During this time he was very drowsy, lying for the greater part of the time in a stupor from which he could be only partially roused. He was constipated, but never vomited. The pupils were at times dilated but always responded to light, though sluggishly. There was frequent nystagmus and almost constant grinding of the teeth. He had at times a tendency to opisthotonus, and once twitching of the right face was noted. The pulse was very weak, for the greater part of the time imperceptible at the wrist, and from 120 to 140 per minute. The respirations were from 20 to 50, and often irregular.

The fontanelle was depressed, and the extremities cold, unless artificial heat was kept applied. The abdomen was not retracted. His drowsy, semi-stupid condition alternated with one of irritability.

He took medicine, food, and stimulants well. During the second week of his illness, until November 21st, his fever gradually subsided, and the temperature was occasionally subnormal, once 95° F. in the rectum. From these attacks of collapse nothing roused him so promptly as oxygen.

His treatment up to this time had been ice-bags to the head, hot bottles to the feet, sodii bromidi, gr. iv., and potass. bromidi, gr. viii., every two hours. It was continued. He now began to improve slowly, was less drowsy, took a little notice of the children about him. His face looked not quite so pinched. The pulse was still very feeble and often irregular. He was not so irritable. Had cut two teeth. By December 5th his cerebral symptoms had nearly disappeared. His drugs had been kept up, as symptoms were invariably worse when they were omitted.

His temperature did not rise above 100° F. He was still very weak and had grown quite thin, but was able at this date to sit propped up in a chair, and once laughed aloud. During the week following he gained nine ounces in weight. On December 11th he was taken, without apparent cause, with all the symptoms of acute dysentery, from which he died on December 19th. The temperature was high, reaching 105° F. or over every evening. Six grains of antipyrine, in divided doses, given within an hour, were administered several times with the most gratifying results in reducing the temperature and allaying the restlessness, without depressing the pulse.

The passages were from six to ten in twenty-four hours; in the beginning they contained much blood. Only once was anything resembling membrane noticed.

Several times, when apparently *in articulo mortis*, he was revived by the free use of oxygen, and it seemed as though there was quite a reasonable prospect of recovery. He sank steadily and died of exhaustion. Decided improvement in the stools was obtained by the use of enemata of acid. tannic., gr. xx., repeated every four hours.

Autopsy, thirty-six hours after death.—Body quite emaciated. Brain: A little more congestion than is usual was found in the meninges. There were some slight adhesions between the dura and pia, on the under surface of the frontal lobe. The pia was opaque and cloudy in two or three small patches over the convexity, but no other traces of recent or old inflammation were discoverable, and no tubercles, though they were carefully sought. Thorax: The lungs showed slight hypostatic congestion and a little recent bronchial catarrh; bronchial glands normal. The heart was pale and seemed rather small for the age. Its walls and valves were normal. About a drachm of clear serum in pericardial sac. Abdomen: Stomach a little dilated, and contained undigested food. Nothing abnormal seen in it or in small intestine till the lower part of the ileum was reached; here was the very slightest degree of congestion and swelling of Peyer's patches. Beyond the ileo-cæcal valve the whole gut was the seat of marked changes. These were most intense in the cæcum. The wall of the intestine was three or four times its normal thickness. The mucous membrane was of a greenish-gray color, and was covered with a false membrane, which could be stripped off in

patches. This membrane existed in the ascending colon, but was not seen beyond the hepatic flexure. The rest of the colon and the rectum were of a pale red color, showing marked thickening and enlargement of the solitary follicles, but no ulcers. The small intestine contained normal yellow fæces; the large intestine greenish mucus and fæces, but no blood. Recent lymph covered the meso-cæcum, but the peritoneum was elsewhere normal. The mesenteric glands were enlarged from infiltration of cells, but showed no tendency to cheesy degeneration. Liver: Size normal; weight nine ounces; a little firmer than normal. Its surface showed white glistening streaks. On section a mottled, reddish-white appearance, not very well marked. Spleen: Nearly twice normal size; weight two ounces; moderately congested; firm. Malpighian bodies not specially prominent. Kidneys: Weighed together one and a half ounce; cloudy swelling of the cortex.

Microscopical examination was made of the large intestines, liver, and kidney. The intestines showed the usual appearances of croupous dysentery seen in the adult, except the presence of ulcers of any considerable size. The false membrane was made up of coagulated fibrin, which covered the surface of the mucous membrane and infiltrated the spaces between the crypts of Lieberkühn, causing considerable compression, but nowhere sloughing. The submucous coat showed a large amount of cell-infiltration, and some fibrin. The solitary follicles were distended everywhere, and many had ruptured, forming small ulcers. The liver showed a perceptible but not very marked increase of connective tissue through its whole substance, with areas of anæmia, and others with slight fatty changes. In the kidneys nothing beyond swelling of the epithelium, and a slight amount of infiltration with leucocytes in scattered areas.

The pathological appearances of the different parts of the large intestine showed, quite conclusively, the beneficial effects of the treatment by injections. In the lower part of the bowel, where the changes are usually the most marked, the mucous membrane presented the least changes, the marked thickening only remaining to show that there had been an active process going on, the severity of which was past. The injections used do not seem to have been large enough to reach the ascending colon and cæcum.

GENERAL TUBERCULOSIS WITH LATENT SYMPTOMS—TUBERCULAR MENINGITIS.

CASE II.—The patient was a female child, aged seventeen months; had been in the Institution only six weeks. The family history was not very clearly tubercular. The father was reported to be suffering from "lung trouble," with considerable cough and expectoration. The mother had had suppurative adenitis in the neck and axilla, the scars of which were still present. Otherwise the history on neither side suggested tubercular diathesis. The child had measles at five weeks, but never any other acute illness. A cough for a long time had existed. On admission the child was rather poorly nourished, quite rachitic, and seemed to be suffering from a recent mild bronchitis. There were some coarse râles scattered through the lungs, the respirations were 64, and pulse 140. The temperature was kept for a few days, but as it did not rise above 100° F. in the rectum it was discontinued. Under a generous diet and the use of cod-liver oil and tonics the child improved very markedly in the next month. She gained in weight, improved in general appearance, the appetite was good, and she got strong enough to push a chair about, which she had never done before. The child was examined with some degree of care with reference to the rickets about ten days before she died. The muscles were then a little flabby, there was pot-belly, an unduly opened fontanelle, and relaxation of the ligaments of the lower extremities, but no cachexia, or anæmia even, and nothing to suggest any serious disease. She had no pulmonary symptoms, and the condition of the lungs was not investigated. She had always been inclined to constipation.

She continued without any perceptible change in symptoms until December 17th, when she was seized with a general convulsion, and the temperature rose to 101.8° F. From this till death, on the morning of December 20th, the convulsions were repeated once or twice a day. The temperature ranged from 99° F. to 102° F., never rising above the latter point. The respirations were about 50 a minute. An examination of the chest was made by the resident physician, and marked dulness found along the spine on both sides. The child was so excited that nothing satisfactory was made out on auscultation. There was only slight cough. The bowels were loose. The treatment was directed to the cerebral symptoms, but was without effect. She died a few hours after having had a convulsion.

Autopsy forty-eight hours after death. Brain: There was moderate congestion of the meninges; at the base along the fissures a few scattered miliary tubercles were seen, but no lymph or pus. The pia was somewhat adherent in places. There was no excess of fluid in the ventricles. Lungs: There were firm, old adhesions over the left lung anteriorly and at its base; none of the right side. The posterior portion of the right lung, middle and lower lobes, was in a state of collapse, uniformly smooth, of a dark red color, non-crepitant, and sank in water. It could be inflated with moderate force. The rest of the lung was emphysematous, and showed miliary tubercles very sparsely scattered over its surface, but no other changes. The upper lobe of the left lung was the seat of extensive disease. Its lower half was consolidated, and on section a small cavity was found in the mammary region, containing one or two drachms of pus. The adjacent lung-tissue was studded with yellowish nodules, varying from a very small size up to that of a bean. The rest of the lobe was studded more or less closely with tubercles, which seemed more recent, while the consolidation below was tough and apparently largely fibrous. The lower lobe, like the right lung, showed extensive collapse behind some emphysema, and a very few tubercles. All the bronchial glands were enlarged, several to the size of a hazel-nut, and one or two were broken down and cheesy at their centres. Heart and pericardium were normal. Liver enlarged, very fatty; weight, twelve ounces. Spleen full, three times usual size; weight, three ounces. Malpighian bodies very prominent. Kidneys showed slight cloudy swelling of the cortex. A few miliary tubercles were scattered over the surface of all these organs. Mesenteric glands were all enlarged, the largest being nearly an inch long. None were cheesy. No tubercles seen in the peritoneum.

There was catarrhal swelling of the mucous membrane of the large intestine, particularly in the cæcum and rectum, and the solitary follicles were prominent. Peyer's patches were slightly infiltrated, but there was no ulceration.

Microscopical examination was made of the lungs, and bronchial and mesenteric glands. The firmly consolidated areas were found to be made up almost entirely of new fibrous tissue. In this were imbedded a good many tubercles, mostly caseous, containing numbers of giant cells. The collapsed portions were free from tubercular changes, and showed almost no evidence of inflammation in the alveoli, the interstitial tissue, or the bronchi. The vessels were considerably thickened. The bronchial and mesenteric glands exhibited the various stages of tubercular infiltration and caseation, and contained, like the lung, many giant cells.

The process in the lung was then an old one, probably of many months' standing; after being quiescent for some time it suddenly took on renewed activity, and became the focus for general infection.

DR. PUTNAM JACOBI asked if it was not possible that the cerebral functional disturbance in Dr. Holt's case was due to the cirrhosis of the liver.

Dr. Holt thought that such was hardly the case. During the period of cerebral symptoms the child took four doses of quinine, which might be an element in forming an estimate of the significance of the symptoms, and it was also to be noticed that during the existence of the cerebral symptoms dentition was going on very actively.

Dr. Putnam-Jacobi remarked that dentition was to be regarded as a disturbing element only in rachitic children.

Dr. Amidon said it was his firm belief that some cases of tubercular meningitis recovered, and he referred to one under his observation, in which recovery took place during the use of heroic doses of iodide of potassium. In that instance there was diplopia, frontal headache, facial paralysis on the right side, excessive photophobia, and maniacal disturbance at night. The patient was an adult, and was in a condition of advanced phthisis, probably tubercular in character, and although her condition was not such as to justify heroic treatment, she was treated by the administration of about an ounce of the iodide of potassium in twenty-four hours. The patient recovered entirely from the cerebral symptoms, and at the autopsy, the patient dying some time afterward, not a trace of meningitis could be found. He had always regarded it as a case of tubercular meningitis cured. The patient gave no history of syphilis, and she had well-marked pulmonary tuberculosis.

Dr. Van Santvoord remarked that in the case of children, marked cerebral symptoms were very frequently coincident with other disturbances, and he had been so frequently disappointed with reference to diagnosis and post-mortem changes that he had refrained from making a diagnosis until he saw the lesion in the dead-house.

Dr. Putnam-Jacobi said that the proximate cause of symptoms in tubercular meningitis was hyperæmia of the meninges and softening of the gray matter around the tubercles and immediately under the meninges. Thus we might suspect tubercular meningitis, and it might be simulated by any cause which would produce hyperæmia of the meninges.

Dr. Van Santvoord had been struck with the extreme latency of the course of tubercular meningitis. He recalled one case particularly, in which the process was of weeks' and even months' duration, and gave rise to marked cerebral symptoms only a few days before death.

Dr. J. C. Peters said he had never seen a fatal case of tubercular meningitis unless there was evidence of tubercules in other organs, and he also thought it was exceedingly rare for recovery to take place if there was tuberculosis elsewhere.

Dr. Amidon remarked that a very trifling lesion in the brain could kill a patient, and that he had been obliged sometimes to hunt with a lens in order to find the lesion which was the cause of death.

Dr. Holt said it had always seemed to him unfair to assume that because a patient recovers it was not a case of tubercular meningitis; because we see recoveries from tuberculosis elsewhere, as in tubercular disease of the bones and pulmonary tuberculosis, and therefore we should never hesitate to attack one of these cases with the hope of curing it.

Dr. Van Santvoord asked if in cases of recovery from pulmonary tuberculosis and tubercular disease of the brain, Dr. Holt would not expect to find some lesion at the autopsy?

Dr. Holt said he did not wish to imply that there was no lesion, but that some trace of the disease would be found.

Dr. Putnam Jacobi remarked that, according to recent observations, iodide of potassium was not regarded as a very heroic remedy in tubercular meningitis.

The President said he was acquainted with a case in which the patient, a man forty-three years of age, was now under Dr. Janeway's care, who considers that he is suffering from tubercular meningitis, and has been for a considerable length of time. The Society had already been made familiar with a part of the history of the case in the fact that it was one which illustrated the ready production of albumen in the urine by any active mental agent.

Dr. Prudden thought it was dangerous to draw an analogy with reference to tubercular meningitis from the healing of lesions in the lungs, because the only way in which the pulmonary cure is effected is by the process going on into the condition of fibroid degeneration. As to tubercle, it is now regarded as due to the presence of a bacillus, which produces inflammation of the tissues which goes over into fibroid change.

Dr. Holt would like to direct attention to the occurrence of simple dysentery in young children. This was the third autopsy which he had made within two weeks in which there was simple dysentery disconnected with any other lesion in the intestine. Goodhart states that simple dysentery is extremely rare apart from lesion of the small intestines. In the two cases mentioned, the dysentery was largely follicular.

Dr. Van Santvoord had seen considerable dysentery in children, but it had usually been follicular; indeed, he did not recall a case in which he had seen croupous dysentery.

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 21, 1886.

Abraham Jacobi, M.D., President, in the Chair.

REFLEX SYMPTOMS IN NASAL AFFECTIONS.

The discussion on the above subject was introduced by the Section in Ophthalmology, through a paper read by Dr. E. Gruening (see p. 122).

Dr. Thomas A. McBride continued the discussion as follows: "I shall ask your attention briefly to a report of five cases of reflex disturbance arising from nasal disease.

"Case I.—L. D——, aged twenty-four, consulted me in the spring of 1882, for migraine. Since 1880, he had been having attacks of migraine, occurring first every six or eight weeks, and within the last winter, 1882, the attacks had become more frequent. He gave a very classical description of the seizures. He is awakened in the morning with pain over the left eye or left parietal eminences, and this increases in intensity as the day passes, occasionally being accompanied early in the attack by 'zigzags,' or 'fortification lines,' of red, green, and white colors, and sometimes hemianopsia. There is also much nausea and some vomiting. The attack lasts usually about eighteen hours, and the next day he is completely prostrated. His family history is decidedly neurotic. I regarded his case as a very characteristic one of migraine.

"After paying due attention to his diet, and regulating his mode of life, and exercise in open air. I placed him upon arsenic and extract of cannabis indica. The extract of cannabis indica was increased from one-fourth of a grain to half a grain within a few weeks, and this he continued to take for some fourteen months.

"The seizures were certainly diminished much in frequency, and occurred about once in two months, and occasionally not for ten weeks.

"At the end of fourteen months he thought that the cannabis induced nausea, the arsenic had been discontinued after a use of some six months. He complained of a constant feeling of nausea, and besides of a strange sensation in his head, which he could not describe or express. His efforts in description reminded me very much of those made by patients to describe the aura of epilepsy, especially the aura of psychical epilepsy.

"The cannabis could not be held responsible for this symptom, but inasmuch as he had so great a repugnance to taking the drug he was placed upon bromide of sodium, a large dose being taken at bed-time, and a small quantity, grs. x., with caffeine, grs. iij., being taken three times a day.

"The attacks of migraine recurred at the intervals of about two months, but the feeling of nausea remained and was almost constantly present.

"Early in 1884 he went abroad and accidentally came under the care of Dr. Hack, of Freiburg. Dr. Hack recognized the existence of post-nasal catarrh, and regarded that as the cause of the nausea, and possibly of the migraine. The patient was under treatment for one month, and since then has been entirely free from migraine and nausea.

"Case II.—Master C——, aged ten and one-half, of neurotic antecedents. For several years has had more or less headache, and this has been so persistent and so severe as to interfere with his schooling, and for some months (1885) he has been kept out of doors, away from all books and confinement. He located his headaches over the upper part of the forehead. Searching for a cause of the headache, I referred him to Dr. Gruening for examination of his eyes. Dr. Gruening had made a thorough examination of his eyes and found nothing abnormal in these organs to account for the boy's headache. He suggested that the headaches might be due to the morbid processes then active in the nasal passages. I referred the boy to Dr. Lefferts, and by appropriate treatment the nasal affection was cured, and since then no headaches have appeared.

"In a note to me this morning, the boy's father states that he has been entirely free from headaches, except now and then, when they seem to be due to excessive exertion or fatigue.

"Case III.—Miss R——, aged twenty-six, of neurotic antecedents. For the last three years or more has suffered from severe attacks of headache and also from supra-orbital neuralgia. The headache was accompanied by the neuralgia, but headache and neuralgia often occur separately. Both neuralgia and headaches occurred at irregular intervals, but the headaches always came on when she was menstruating, and as a rule the neuralgia accompanied it.

"The headache was located over the upper part of the forehead, verging toward the vertex, and was also located either over one parietal or to the parietal eminences.

"The neuralgia usually affected the left supra-orbital branch, sometimes both, sometimes only the right.

"The attacks began usually in the morning and were accompanied often with nausea, sometimes vomiting. There was no disturbances of vision. The patient suffered from lithæmia, complained somewhat of nasal catarrh, and, as she was fond of music, was over-anxious in regard to her voice, which she thought was affected by the nasal catarrh.

"Dr. Gruening examined her eyes and found, I believe, slight hypermetropia, which was corrected.

"I referred her to Dr. Lefferts for treatment, and after he had cauterized a few times the hypertrophied mucous membrane of the inferior turbinated bones very great improvement was observed as regards her headaches and neuralgias. Since the completion of the treatment of the nasal condition she has been entirely free from all headaches and neuralgia.

"Case IV.—Mrs. R——, aged fifty. For many years had attacks of hemicrania at time of menstruation. Since the menopause, which occurred at forty, the attacks of hemicrania have appeared at intervals of two to six weeks. For the last ten years she has suffered very much from hay fever. Last August she placed herself under the care of a rhinoscopist in a neighboring city, and the result has been that since the treatment she has had no return of the hay fever, and has had no attacks of hemicrania.

"Case V.—Mrs. B——, aged thirty-six. At intervals in her married life, when she has been in poor health, she has complained of difficulty in swallowing liquids, and of regurgitation of food into the mouth. This regurgitation takes place sometimes immediately after swallowing, sometimes not for twenty minutes or longer after the food has been introduced into the stomach. Oser has described this condition under the head of Rumination or Merycismus, in his lectures on 'Die Nervosen des Magens.' Four years ago she was under treatment for post-nasal catarrh abroad, and now suffers more or less from the same trouble. Three weeks ago she came under my care. She was anæmic, and had evidently some gastric catarrh. I ordered for her tonics, arsenic and iron, and dry diet. On the 12th it occurred to me to suggest the use of a spray of cocaine, four per cent., to the nasal passages, and since then she has been entirely free from the difficulty of swallowing and the regurgitation. The treatment in this case is of too recent a date for one to predicate the result as due to the effect of the cocaine spray apart from the psychical effect, since we know that this condition of rumination or merycismus is often present in hysteria, and this patient, although without the positive signs of hysteria, had a tendency to it.

"I have not referred in the above cases to the condition of the nasal passages, which has been assumed to be the exciting cause of the nervous disturbances, for the reason that I was not competent to do so. When asked to make this communication I objected, thinking that it would be better if the report came from the rhinoscopists—the specialists to whom the cases were referred for treatment. I can, therefore, say nothing in regard to the condition of the nasal passages which were accompanied by reflex disturbances. I have not reported cases of asthma, or certain cures of dry bronchitis, for the reason that such cases are acknowledged to-day to be of not unfrequent occurrence."

Dr. Beverley Robinson continued the discussion (see p. 120).

Dr. Goodwillie presented three wax models, which illustrated the morbid conditions found in (1) a case of deviation of the septum, with hypertrophy of the mucous membrane covering the turbinated bones; (2) a case of complete closure of one nostril, and (3) a case of "hay fever," in which there was a decided hypertrophy of the nasal mucous membrane over the turbinated bones.

In all these cases the patients received marked relief from the reflex symptoms by the removal of the abnormal conditions in the nasal passages, which was readily accomplished by means of revolving knives, worked with the dental engine, and by the aid of the galvano-cautery.

Dr. Baruch referred to six cases which he had treated successfully by treating the mucous membrane of the nasal passages; one of reflex cough, two of headache, one of peculiar reflex pain in the throat, and one of asthma. He used the galvano-cautery. Dr. Baruch thought the matter of diagnosis was simple, as the enlargement of the lower turbinated body could be readily recognized, the only difficulty being that the swelling was sometimes absent temporarily; in such cases it could be readily restored by irritation with the probe.

Dr. H. Schweig said that while the galvano-cautery, when properly used, would give brilliant results, it was an agent which by no means could be easily used by those unaccustomed to manipulate in the nasal passages. To be most successful the cavernous tissue should be destroyed, but not at the expense of the secreting surfaces, and the destruction should by preference be made from within outward. Employ only a dull-red heat, puncture the cavernous tissue, and through the small opening sweep the instrument around beneath the surface, and the best results will be secured.

The President alluded to a large number of obser-

vations which he made some twelve or fourteen years ago, and, so fara s he knew, reference to similar observations had not anywhere been made.

These observations related to the influence of catarrh, hypertrophy, and other changes affecting the nasal and pharyngeal cavities, on other parts of the nervous system not mentioned in the present discussion.

It was well known that a large number of little children, half grown, and grown-up people have peculiar bad habits, so called, of winking, frowning horizontally and vertically, drawing up the nose, twitching different parts of the face, shrugging the shoulders, one or both, etc. Such cases are frequently set down as due to bad habit, but they should be studied with reference to the origin of these irregular movements. It had always seemed to him that it was not natural for a little boy to make these motions without some occasion; the cause, however, cannot be so easily determined.

Some of these cases appear to be local chorea minor, and in several instances he had seen the movements terminate in *general* chorea minor.

About twelve years ago his attention was first drawn to the occurrence of hemicrania, left or right, when there is chronic pharyngitis and amygdalitis, by a small pamphlet written by Lorent, of Bremen, who associated these conditions. Dr. Jacobi found that the observation was correct with reference to a number of cases, and from that time he had studied all cases of chronic nasal and pharyngeal catarrh with swelling of the lymphatic glands, and had found that, in hundreds of cases, the local chorea, the involuntary convulsive contractions, or contractions of the same kind brought on by some intended muscular movement, was associated with conjunctivitis, rhinitis, pharyngitis, or with enlarged tonsils, either congenital or acquired, or both.

In other cases of local chorea, which will ocasionally terminate in general chorea, he had found chronic nasal catarrh of the same description given to-night, and with chronic pharyngitis, and with chronic rhinitis without chronic pharyngitis, or the opposite; in many cases it is difficult to say which is the original disease.

The pharyngeal tonsil is frequently overlooked when studying these cases. It is well known that this tonsil is not infrequently the cause of retro-pharyngeal abscess, and it is with cases of abscess that it has been most extensively studied. Inflammation of the pharyngeal tonsil always causes general rhinitis and pharyngitis. The principal book on this subject is a recent publication by Trautmann, who reports one hundred and fifty cases of enlargement due to chronic or subacute inflammation of the pharyngeal tonsil. This author connects it with a number of symptoms such as are described in connection with chronic pharyngitis and rhinitis, and particularly alludes to migraine, which was present in eighty-seven of the one hundred and fifty. Of the eighty-seven, eighty-five were cured by destroying entirely or partially the pharyngeal tonsil; the others were treated in the same way, but were not cured; one of these was complicated with polypus.

These facts show that the whole surface of the nasal cavity is liable to give rise to these reflex symptoms which have been alluded to by the previous speakers; it may be the pharyngeal tonsil, etc. Frequently it appears that it is only one small spot w ich requires treatment, and all the rest will take care of itself.

The remarks concerning local chorea resulting from chronic and subacute pharyngitis and rhinitis the President regarded as only preliminary. He had not published any of his cases; in fact, he had been of the opinion that every one must have noticed them. But it appears that it is not so, and he gave the observation for what it was worth, and recommended those whose attention had not been drawn to the subject to study cases with reference to this point, and to seek the result of the simple treatment.

The Academy then adjourned.

Correspondence.

OUR LONDON LETTER.

[illegible]

MR. HUTCHINSON'S LECTURE ON SYPHILIS AT THE MEDICAL SOCIETY OF LONDON. THE CASE OF DR. TOM BROWNE.

[illegible]

MR. HUTCHINSON is such an acknowledged authority on syphilis that his "Lettsomian Lectures" have been looked forward to with unusual interest. His first lecture was delivered on Monday evening last in the presence of a large audience. In this he enunciated afresh many of his published views, and also brought forward some original observations and opinions.

On the question of the mutual relations of the different forms of primary venereal sores, Mr. Hutchinson may be termed a unicist. He regards soft sores as an appanage of syphilis, and thinks that the poison which produces them may be only a specialized product of inflammation and not a specific virus. He combated the generally received view as to the uniform character of soft sores. If, he said, we placed in one group all the sores which do not harden and which do not infect the system, we should find the typical characters of the chancroid present in but a small proportion of them. This want of uniformity was a strong argument against specificity. Another equally strong argument was that the true chancroid on the genitals was seldom seen except in those who had already had syphilis. With regard to prognosis, if a person who had never suffered before contracted a venereal sore of any kind it would probably lead to syphilis. Mr. Morgan's statistics were quoted in support of this conclusion. The experiments of Morgan, Lee, Gascoyen, Bidenkap, and others were quoted as to the production (in those who had had syphilis) of chancroids by inoculation with syphilitic secretions and purulent secretions from indurated sores which had been made to suppurate by artificial irritation.

Mr. Hutchinson then stated afresh and expanded his already published views as to the relation of phagedæna to syphilis. Phagedæna, as we see it in connection with syphilis, he regarded as being almost invariably of spontaneous origin, *i.e.*, caused by syphilitic inflammation and not by phagedænic contagion. Mr. Hutchinson compared it with the chancroid, believing that, like it, it is a modified form of syphilitic inflammation. I may remark in passing, that most British surgeons believe that phagedæna is a more frequent accompaniment of the chancroid than of indurated chancres. It will be seen from the above that Mr. Hutchinson teaches the reverse. He also holds that hospital phagedæna originates from syphilis, and expounded this view at some length in his recent lecture. The disease was very contagious and spread by contagion only, but it never led to constitutional syphilis. Accepting the hypothesis of its syphilitic origin we had, said the lecturer, a parallel fact to what (in his view) occurred in the case of chancroid. A specialized contagium (pus) had been bred up, which could produce its like wherever inoculated, but did not contain the virus of syphilis.

Mr. Hutchinson also protested against the popular doctrine in regard to another matter. It is generally believed that inflamed buboes following venereal sores occur almost exclusively in connection with soft sores. In private practice, said the lecturer, it was very rare that we had to do with inflamed buboes, but of late years it had so happened that almost all the cases of suppurated bubo which he had seen were cases of syphilis. It was not very exceptional for the typical chancroid to cause no enlargement of the glands at all. The practical inference drawn was that we were on unsafe ground in assuming that scars in the groin implied absence of constitutional infection.

The subject of second attacks was then considered,

For a second attack to occur it has usually been considered necessary for a long interval of years to elapse, but Mr. Hutchinson said he had seen a well-characterized chancre due to fresh contagion, within a year of the first, and before the patient was well rid of his symptoms. He had repeatedly seen them in those who still suffered from reminders of their former attack. It had been proved by experiment that in occasional instances fresh inoculations on patients suffering from syphilis may produce a certain degree of induration, although, as a rule, they failed.

Incubation periods were then discussed and the opinion expressed that they were really longer than has generally been believed. "If by incubation period," said the lecturer, "we mean, as I contend we ought to do, the interval between contagion and the production of an induration which can be diagnosed, then I believe we shall seldom find it less than five weeks, and more often six. If we date to the first appearance of a sore, then it will be a week or ten days shorter, for the development of hardness takes that time."

Another interesting point then referred to was the fact (first noted by Mr. Hutchinson himself) that chancres might recur. It was quite possible for indurations to develop in the retrocoronal fold of the prepuce, which assumed the most exact resemblance to hard chancres, but which were not consequent on any fresh contagion. They occurred to those who had had syphilis and usually on the site of former chancres. They might occur repeatedly to the same individual. They usually appeared within five years from the primary infection. They mostly retained throughout the most exact resemblance to the ordinary collared chancre, and they were often wholly without ulceration. Mr. Hutchinson said he had also known a chancre to recur in a case in which the disease had been due to vaccination.

The frequent occurrence of cases in which syphilis followed what was considered to be only gonorrhœa suggested the suitability of recognizing what we might call gonorrhœa-syphilis. There was no danger now that this name should mislead us into adopting Hunter's erroneous generalization. These cases might be explained on the supposition that the particular virus of syphilis might exist in gonorrhœal pus. If a patient, the subject of secondary syphilis, should contract gonorrhœa no doubt the virus would pass into the discharge, since we knew that it was present in the blood, and found its way into all products of inflammation. Such a person would very likely convey to another gonorrhœa immediately, and a chancre four or five weeks later.

Mr. Hutchinson brought his rather long but very interesting lecture to a conclusion by a brief reference to the subject of syphilis conveyed in vaccination. That the disease may be transmitted by vaccination *with clear lymph* from a syphilitic person he now regards as an established fact. He bases this belief on the result of some experiments made by one of our public vaccinators (on himself) a few years ago. The gentleman referred to finally produced an outbreak of constitutional syphilis by repeatedly vaccinating himself *with clear lymph only* from syphilitic infants.

Dr. J. Crichton Browne has been knighted. Dr. Browne has been known for many years as an able psychologist, but was brought into special prominence a short time ago by his report on "Overpressure in Board Schools." The Liberal Government, then in power, endeavored to suppress the report, and, when printed, to discredit it by printing along with it a rejoinder by Mr. Fitch, one of the Inspectors of Schools. The report, however, carried conviction to its readers, most of whom will be glad to see that the present Government has been ready to accord Dr. Crichton Browne the credit he deserved.

THE USE OF COFFEE sometimes causes pruritus vulvæ and pruritus ani.

THE COMMITMENT OF THE INSANE.

TO THE EDITOR OF THE MEDICAL RECORD.

I MUST take exception to certain statements made in your editorial on "The Commitment and Management of the Insane," in THE MEDICAL RECORD of January 9th. You state that physicians, wishing to have their certificates of insanity signed, are subjected to vexatious delays and personal annoyances, and that the doctor is often obliged to fee the clerks and court-attendants to facilitate matters.

I have been the Examiner in Lunacy for the Department of Public Charities and Correction for the past eight years. As I commit, on an average, fully one hundred patients a month, I am compelled to go to court almost daily. In all that time I have never given a fee to any court-attendant, even of the most trivial nature, nor has any such thing been hinted to me.

In regard to the judges, I have found them agreeable and accommodating, many of them signing my papers while holding court, during an interval in argument between counsel. During vacation time in summer, when there are only a few judges in the city, I may have to wait a little, but no longer than a member of the bar. In all my experience, I have had only one judge refuse to sign my papers. He refused on the ground that it was not constitutional to deprive a person of his liberty except after a trial by a jury, even if he was insane. A number of times, where the cases were urgent, I have had my papers signed by the judges at their residences at night.

WILLIAM L. HARDY, M.D.

353 WEST TWENTY-EIGHTH STREET,
January 12, 1886.

[We can only say that Dr. Hardy's experience is not that of many others, as reported to us.—ED.]

THE PLURAL OF LARYNX.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In all sciences the demand for an exact nomenclature has at some time been felt, and, to a greater or lesser extent, this demand has been satisfied, but much is yet to be done before the physician or surgeon can claim for his science a perfect vocabulary. Many questions regarding the spelling and formation of medical terms constantly arise, and if a layman occasionally offer a suggestion, it will, without doubt, be taken in good part by his professional friends.

A prominent laryngologist of London saw fit to criticise a confrère of Brooklyn for his use of larynges as the plural of larynx, the Englishman claiming larynxes to be the correct form, at the same time clinching his argument by affirming that a Latin scholar, on whose judgment he relied, had assured him of this. Now, though this evidence may have seemed all-sufficient to Dr. ——, yet there may be some incredulous readers of this journal who will demand some more satisfactory evidence, and this it is our present endeavor to furnish.

Of these two forms, which is correct, or, if both be correct, which is to be preferred? If we turn to the dictionaries we shall obtain no assistance, for, without exception, they omit all mention of a plural of larynx. In default of direct evidence we shall have to fall back upon the rather dangerous method of reasoning from analogy. Turning over the leaves of our mental vocabulary, let us halt at the word phalanx, and see whether it will not help us out of our difficulty. Like larynx, phalanx is derived from the Greek, and has in the genitive φαλαγγος; the γγ is equivalent to English ng, γγ being an assimilation of ν with γ, a process quite familiar to Greek scholars. But it does not necessarily follow that the English word has accepted the oblique cases of the Greek noun, as well as its nominative case. Very frequently an English word derived from the Greek forms

its plural after the English fashion, but a particular analogy is always to be preferred to a general one, and if we can find authority for phalanges, we shall have to decide in favor of larynges also. Webster and the Imperial give the plural phalanges as an anatomical term, hence larynges.

The forms derived from phalanx and larynx also materially assist us in our demonstration, for without exception ng is employed, as phalangeal, phalanges, laryngeal, laryngitis, laryngology, etc. An appeal to the cognate dialects reveals the same fact, Latin having the plural phalanges; French, the form laryngi; Italian and Spanish, laryngio.

The arraignment of these arguments would seem to decide the case in favor of larynges, although it is not intended to dispute Dr. ——'s perfect right to use larynxes, "because it's English, you know." We all know the proneness of the English scientist to conservatism, especially in regard to suggestions from this side of the water; we shall not be surprised, therefore, if larynxes still holds its place in English hearts.

Hoping that this note may find a place in your journal, I remain respectfully yours,

DANIEL KILHAM DODGE, A.M.

COLUMBIA COLLEGE, January 8, 1886.

P.S.—Since writing the above I have found in Goold Brown's "Grammar of English Grammars" the plural form larynges, with no mention of larynxes. D. K. D.

CONTROLLING SEX IN GENERATION.—Dr. E. A. Cobleigh, of Athens, Tenn., writes: "In your issue of December 26, 1885, is a review of a new book by a Mr. Terry, entitled 'Controlling Sex in Generation.' The author assumes that 'at the generation of male offspring the mother must be in a higher degree of sexual excitement than the father,' and conversely. Now, facts are stubborn things, no matter what theory they run against, and this they often do to a well-grounded idea. My experience as a practitioner of medicine leads me to strongly doubt Mr. Terry's hypothesis. One fact does not controvert an argument, for it may be an exceptional one, but several similar antagonistic facts do tend powerfully that way. I have seen several such, two of which are positive facts which oppose squarely the author's assumption. Now, let me ask, is it not the experience of every physician that no inconsiderable number of females in a community may be found who are either *naturally* and wholly devoid of any sexual propensities whatever; or, if not minus this propensity, are at any rate its possessors only to a feeble extent? Such has been my own observation. To this may be added a quota of women who abhor the sexual act through pathological conditions of the sexual organs which render it inconvenient, or even painful,—those suffering from 'dysparennia,' as Barnes calls it. Now, these women conceive like other women, and bear male offspring, as I have more than once had knowledge of in my practice. And, to be more explicit, I will cite three just such cases which I now call to mind, the inside history of which I am thoroughly conversant with. I know two married ladies, in good social position, each of them the mother of two boys and one girl, the girl in both instances being the youngest. One of these women bore both her boys before she ever knew what sexual excitement was, the girl being the fruit, however, of a sexual act participated in fully by both the wife and the husband. In the other case the lady does not, to this day, experience any pleasure whatever in the sexual act. Here were four boys conceived by two females, to my knowledge (for this condition of affairs was a cause of regret in the domestic circle), both of the women being at the time in a mere condition of passive submission. In a third instance a woman, in the highest circles of society, bore an only child under the same circumstances, that child being a boy. I might adduce other instances, but these are sufficient to rebut the hypothesis which I am dealing with. Indeed, I think this theory might rank with a superstition harbored by two men of my acquaintance, one of them a physician himself and the other a clergyman. They believe that the position of the woman during and immediately after the act (on the one side or the other) accurately determines the sex of the resulting fœtus. Both have large families, and they think they have demonstrated a scientific fact by their own experiences.

ANATOMICAL CURIOSITIES.—Broesicke describes in *Virchow's Archiv* the following anomalies which he found on the dissecting table: 1, Congenital union of the kidneys by an S-shaped band; 2, a third median laryngeal ventricle; 3, a diverticulum in the lateral wall of the pharynx communicating with the Eustachian tube.

EXTRAORDINARY FECUNDITY.—We borrow the following questionable story from our otherwise truthful contemporary, the *Raccoglitore Medico*. A certain Maddalena Granata, forty-seven years of age, was married nineteen years ago. Her first child, a girl, was born after nine months, and lived to be eight years old. At the next birth six male fœtuses were brought forth, one of them being apparently in the sixth month, the others younger. The third pregnancy resulted in three more males of seemingly different stages of development. The fourth trial resulted in three more fœtuses, also males, at the sixth month. The fifth pregnancy resulted in twins, females, born at term, one of whom is still living at the age of twelve years. This occurred in 1873, and from that time up to the present Signora Granata has turned out no less than forty-five more fœtuses of the masculine gender, making a grand total of sixty in nineteen years! The woman is in excellent health, and is able to do her full share of work in the fields along with the other patients. The reporter adds that any one who does not believe this tale may inquire of Dr. Raffaele de Sanctis, of the rione Liporta, in lower Nocera, where this remarkable woman lives.

PRIORITY IN HYDROPHOBIA INOCULATIONS.—At a recent meeting of the Royal Academy of Medicine of Rome, a committee was appointed to collect evidence in support of the claim for priority in hydrophobia inoculations made in behalf of Dr. Cappello, of Rome. Before making any great claims it would be well to have the value of the method determined.

THE GERMAN DISPENSARY.—The twenty-eighth annual report of the German Dispensary, No. 137 Second Avenue, shows a total of 33,496 patients treated during the year 1885. The total number of consultations was 79,252, and the average number of consultations by each physician was 2,401. The number of patients treated since the dispensary was founded reaches the large figure of 463,417. The new building donated by the late Mrs. Ottendorfer has proved itself well adapted for its purpose, and of sufficient capacity for the accommodation of the patients, of which, on a busy afternoon, there were sometimes nearly 400. It is gratifying to learn of the number relieved in this institution, but one cannot but ask how many of these 33,496 patients might have been able to pay some physician a moderate fee for advice and treatment. Some of them, no doubt, could have done so.

TOLERANCE OF MORPHINE IN AN INFANT.—A correspondent, from Winnipeg, writes: "I have a case of spina bifida, with hydrocephalus, in a child four and a half months old. The spinal deformity includes the last three lumbar vertebræ. There is complete paralysis of all parts below the seat of lesion, including the sphincters, and also double talipes varus. The child, a little girl, has seemed to suffer excruciating pain ever since birth, keeping up a continual screaming. As we hoped death would soon terminate her troubles, no operation or treatment of any kind has been instituted, except the use of narcotics to allay pain. At the present date she takes half a grain of sulphate of morphia a day, and this has only a quieting effect. She takes one-sixth of a grain for a dose, and is actually thriving on it, so that I am afraid some operation will have to be performed, if only to give her a chance of dying."

HYDROBROMATE OF HYOSCINE.—Dr. P. M. Wise, of the Willard Asylum for the Insane, writes: "Such conflicting reports have appeared recently concerning the value of this substance as a hypnotic, in substitution for the coarser alkaloid hyoscyamine, as to lead one to suppose that the drug used by the several writers was not of a uniform nature. The hyoscine used at the Willard Asylum, where its action has been carefully observed for a number of months, was obtained through Merck's authorized agents in New York, and was delivered in the original packages. The preparation of the aqueous solution was made with great care, and was kept only in ground glass stoppered bottles. The conclusions reached by the medical staff of the asylum in respect to its value as a hypnotic are nearly identical with those of Drs. Peterson and Langdon, as reported in THE MEDICAL RECORD of September 19, 1885. It was found that it disposes to sleep indirectly after several hours, when given in sufficient doses to produce its marked physiological effect, such as muscular relaxation, and, occasionally, stupor; but that it cannot be regarded as a hypnotic in its proper sense. Its use in active mania and melancholia was not attended with desirable results. In cases of insomnia it failed in doses short of producing its disagreeable effects—midriasis and dryness of the throat and mouth. In our experience it does not possess the value of hyoscyamine in any of the uses to which the latter is ordinarily applied. It has been used in doses varying from $\frac{1}{200}$ to $\frac{1}{75}$ of a grain." Dr. Wise adds that he has also tried the drug in whooping-cough in a child nine years of age, without obtaining any appreciable benefits as regards either the paroxysms of coughing or the insomnia.

A NEW INSTRUMENT FOR MAKING VESICO-VAGINAL FISTULÆ.—Dr. Jacob Michaux, of Richmond, Va., sends a description of an instrument which he has devised for establishing vesico-vaginal fistulæ when, in cases of cystitis, this condition is desired. The instrument, called a vesicotome, consists of two separate blades which, when desired, are locked in the same way as the ordinary obstetrical forceps. One of the blades is armed with a punch, either oblong, elliptical, or round, as may be desired, and the other has a slight depression on a lead surface to receive the sharp edges of the punch. The latter blade is first passed into the bladder, and the handle of the instrument raised so as to cause the tip of the blade to bulge into the vagina. Then the other blade, armed with the punch, is passed into the vagina, the handles are locked and then firmly pressed together, so as to cut out a clean piece the exact size and shape of the punch. The patient is to be in the Sims' position, with a Sims' speculum in the vagina.

ABSORBENT COTTON AS A COVERING FOR ELECTRODES.—Dr. J. H. Greene, of Dubuque, Ia., writes that he has been using absorbent cotton as a covering for electrodes, in the place of sponge, for the past two years. He uses an electrode formed of a rounded polar surface fitting into a hard-rubber retaining ring. The absorbent cotton is folded in rectangular form and passed between the ring and the polar surface. The latter is then screwed down, pushing before it the cotton until the latter is arrested by the rubber ring. The cotton fits smoothly over the polar surface, and the whole makes a neat and compact electrode.

A SINGULAR CASE.—At a meeting of the Medical Section of the Academy of Medicine in Ireland, says *The Lancet*, held on the 18th inst., a very remarkable specimen was exhibited by Dr. J. Magee Finny. It was an example of an ulcer of the stomach, which perforated the left ventricle of the heart and caused death by hemorrhage. The subject of this interesting example was a lad aged seventeen, of a somewhat strumous constitution, who was admitted into hospital under Dr. Finny's care about two months since, and died early in December. During his stay in hospital pain was complained of about the cardiac region, and pericarditis was diagnosed; but, strange to relate, there were no symptoms of any gastric irritation, neither pain nor vomiting. On the day death occurred the patient passed blood by stool, and a post-mortem examination showed that the stomach was entirely filled with blood.

MODERATION IN BONE SELLING.—The Austrian Minister of Instruction recently sent a communication to an association of Viennese physicians, requesting, on "legal, moral, and sanitary grounds," the sale of human bones and anatomical preparations be as far as possible restricted. An answer was returned to the effect that there was nothing illegal, immoral, or unsanitary in the sale of such articles, and that if there were, their sale should not be limited, but absolutely prohibited.

A MALE MIDWIFE.—A story is told in the *Journal de Médecine de Paris*, of a young married woman whose notions were so strict that she refused to have a physician attend her in her confinement, and insisted upon having a midwife. The family physician, having a sincere interest in the young lady, and being unwilling to intrust her to the care of a midwife, conceived the idea of sending a young medical friend whose face was beardless though his knowledge and skill were great. The young doctor accordingly dressed himself in female attire, saw the patient, and safely delivered her of a promising child. But he was not allowed to escape without a severe trial, for he was consulted by all the female members of the family, one after the other, for certain little tumors and other blemishes on various parts of the body which they had been unwilling to exhibit to their family physician. His wounded modesty was healed, however, by a plaster in the shape of a five hundred franc note.

MICROBES IN LAUDANUM.—Dr. G. Puerta writes in *El Siglo Médico*, that he has discovered a bacillus in a number of specimens of laudanum examined by him, which bears a striking resemblance to the comma bacillus. He thinks that care is therefore necessary, in examining the stools of patients with diarrhœa, to see that laudanum has not been given, as then bacilli would be found in the dejections and a diagnosis of cholera might be erroneously made.

METHODS OF DIAGNOSIS.[1]

BY LAWSON TAIT, F.R.C.S.,

BIRMINGHAM, ENGLAND.

AT a meeting of the New York State Medical Society, last February, my friend, Dr. Vander Veer, paid me a compliment of a most unusual kind, and for which no words of mine could possibly form an ample recognition. As I read the paper in which he described his visit to me, and what he saw while he stayed there, I had some difficulty in recognizing that the points upon which he laid great stress really deserved the prominence in which he had placed them. No one, however, can be a judge of his own work, and I therefore accept Dr. Vander Veer's valuation of mine in a spirit as generous, I trust, as that which he has displayed in describing it.

Many of the sentences in Dr. Vander Veer's paper have given me food for thought, and I think that in many respects I have to be grateful to him for improvements in my details, which have been suggested to me merely by seeing my methods described by one who was strange to them. One paragraph in particular has given rise to much introspection, and at first it alarmed me very much, because I felt that if the criticism were deserved (and this sentence really stands alone in the paper as being a criticism in the ordinary sense of the word), I was in all probability doing harm to my patients, and certainly was running the risk of setting a bad example to others whose opportunities were not so great, and whose condition of practice was not so peculiar as my own.

The paragraph I speak of is as follows: "Mr. Tait does not give very much time to the examination of his patients, as a general thing. His manner shows him to have unbounded confidence in making an abdominal section, then treating whatever he may find." I do not believe for a moment, after very careful thought upon the subject, that Dr. Vander Veer arrived at the conclusion that my method of diagnosis was careless and irregular. It is perfectly true that I have unbounded confidence in making an abdominal section, and by long practice have achieved a facility for treating whatever may turn up. But I have satisfied myself that, though the time which I give for the purpose of examination of any particular patient, or of my patients in general, may be short; that that time is only relatively and not actually short, and I desire to say something about my methods of diagnosis in this paper, not merely for the purpose of defending myself from what would appear to be something like a charge of recklessness, but far more to speak, as well as I am able, upon the processes of diagnosis which are peculiar to the practitioner who is not engaged in clinical teaching.

I fancy that the difference must be very much that which would exist between the process of an artist who is also a teacher of drawing, and one laboring entirely in the studio. A teacher must not only be precise and methodical, but he must do everything largely by routine; and to show his pupils how to accomplish their work accurately, he must not only lay down line after line and wash upon wash, but he must teach and give examples at a level which will suit the least instructed and dullest of his pupils. It must, of course, be essentially different in the case of an artist who works purely in his studio, and solely for the purpose of producing, to the exclusion of anything like instruction. I have actually gone to the trouble of watching the technique of two painters—one of them a teacher, the other merely a producer—precisely for the purpose of investigating this point, and I am quite certain that what I have seen about them is equally true of artists in surgery.

It has been my misfortune never to have been a teacher, and therefore I have found, since my attention has been drawn to the matter by Dr. Vander Veer's paper, that I come to my conclusions in ways which are altogether different from those adopted by men who are engaged in the practical instruction of pupils. I was immensely struck with this during my recent visit to the Medical School at Edinburgh, where clinical teaching of medicine and surgery has been brought to its greatest perfection. There I found men who have been my life-long friends, men more or less of my own age, who are trained teachers as well as accomplished practitioners, differing from me precisely in the directions which I have already indicated. There can be little doubt that the training of a teacher inculcates habits of precision and accuracy such as can be acquired in no other way. But, on the other hand, it involves methods of thought, and particularly methods of diagnosis, which, whatever else they may do, involve very protracted methods of reasoning, and a considerable expenditure of time.

I found that their methods were pretty much to my own in the same relation as the multiplication table stands to the arithmometer. They arrived at conclusions identical; but my own methods—some of which are practically inexplicable, because I hardly understand them myself—certainly involve a great saving of time and trouble. Let me instance the method of diagnosis which we call palpation. An abdomen is submitted for examination, uniformly distended, and the question comes to be, first of all, as to whether the distention is due to an intra- or extra-peritoneal cause; as to whether this cause is a collection of fluid or the growth of solid matter; whether these causes may be mixed, and in what relation they stand to one another; what organs may be concerned in the treatment of the enlargement, and fifty other questions of more or less importance in deciding how the disease may be dealt with. A teacher approaches such a subject as this from an altogether different view, and in an altogether different way from those of a man who is engaged exclusively in practice. The teacher's desire is not only that he should arrive at a correct conclusion upon all the questions, or as many of them as are capable of solution, but that fifty or more young men, devoid of experience, may see the reasons and follow his reasoning upon all of these said questions. As these fifty men will move with progressively-increasing slowness in their mental action, it practically comes to this, that the process of diagnosis on the part of clinical teachers can only be made at the rate possible for the dullest pupils.

In the practice of the practitioner there is no such retarding influence, and his methods and his conclusions occupy just as much time as his mind would require to make them. An example of this difference I noticed in the case of a very eminent teacher, whose hands wandered over an abdomen, noting with care, percussing

[1] Read before the Medical Society of the State of New York, February 2, 1886.

uniformly and extensively, seeking everywhere and in all directions for fluctuation, and coming to his conclusions after an examination which occupied over fifteen minutes. He was not at the time engaged in teaching, because we were by ourselves, and he is not a man whose mental powers are by any means slower than my own; but the habit of teaching was on him, and my own conclusions, which were identical with his, were made in exactly one-fifteenth part of the time. From this experience, as well as some others of less note, I derived much comfort, because I felt that Dr. Vander Veer's statement was capable of very satisfactory qualification.

I need not say that, in addition to the absence of the retarding influence which teaching must exercise, another qualification of Dr. Vander Veer's views lies in the fact that my practice is restricted in area to an extent which has probably never before been attempted. Even the practice of ophthalmic surgery may be regarded as a much wider field than that which I occupy, for I limit my work absolutely to the surgery of the abdomen and pelvis, and into this there cannot be brought any of the diverting attractions such as are formed by the refraction cases among diseases of the eye. This restriction of area, coupled with the very large number of cases in my practice, gives me as much facility in the matter of diagnosis as has been accorded to me in the matter of treatment, if the evidence of Dr. Vander Veer, Dr. Dudley, and others is to be accepted as affording a fair criterion.

It is true about every human handicraft, that by restricting the area of production there is secured a much larger experience within that area, and the workmanship which results is very much better. This division of labor must lead to the same improvements and developments in surgery as it has done in everything else. I therefore have to plead that what seemed to Dr. Vander Veer, and I know has seemed to others, but a short and possibly incomplete system of diagnostic methods, is really, so far as results are concerned, quite as complete, if indeed it is not more so, than methods which seem to be far more elaborate and are certainly much slower. Let me give a few examples, such as I have been able to establish in my own belief after much search, as to how a skilled workman may do with his fingers what the inexperienced may require special tools to enable him to accomplish. In the gynecology of twenty years ago, which was pretty much the period at which the great master of the art left it, there still remained a survival of the battles which waged for many years concerning the use of the speculum and the sound. The school of French gynecology was charged with an altogether improper, and indeed, as it was urged, a very indecent frequency in the use of the speculum. On the other hand, the English school, with Simpson at its head, was fully as often and as loudly charged with an improper use of the sound. The conclusion that I have come to concerning both of these instruments and both of these disputes is, that both sides were right and both were wrong.

It is perfectly impossible for any novice in the diseases of women to obtain an accurate notion as to the condition of the vaginal mucous surface of the os and cervix, and to some extent the interior of the uterine canal, without the constant, I would almost say the invariable, use of the speculum. It is also quite as impossible for that novice to form any notion as to the position of the fundus, or the relations of the uterus with the pelvic tumor, without the employment of the sound. But no practitioner of gynecology can possibly be regarded, at least by me, as an accomplished specialist who uses either one or the other of these instruments with great frequency. I have found in my own practice, that just as my experience increased so did both of them become unnecessary, until, concerning the speculum, it is a fact that, unless I want to do some operation, or make some special investigation within or beyond the vaginal cavity, the speculum is never employed at all; and for the discovery of the position of the uterus and its relations, the sound has almost ceased to be an advantage.

It is perfectly impossible for me to convey by any kind of description how I can tell, by the touch, an inflamed vaginal mucous surface from one that is healthy; neither can I describe the feeling that the everted surface of the cervix gives to me which declares the condition of chronic endometritis. But I know that my educated finger-tips can make this distinction. If, on the other hand, I discover a pelvic tumor, long practice enables me to tell with almost perfect certainty, and without the use of the sound, that it is a retroverted fundus, or adherent tube or ovary, or by its fading away toward the broad ligament, on one aspect of the uterus or another, that it is an intraperitoneal hæmatocele; while the peculiar resistance of a myoma conveys to my mind an accurate impression which needs no probing of the uterus to substantiate So a cyst reveals itself in a way I cannot communicate. As a result of all this I very rarely use the sound.

As a matter of fact, I have found that these two instruments, the speculum and the sound, as methods of diagnosis, have been productive of uniformly more harm than good. That a blennorrhagic discharge from the vagina of any patient requires the introduction of a speculum is one, I am fully persuaded, of the stock beliefs of the great bulk of general practitioners. But it is certain that nothing of the kind is requisite, and a very large amount of mischief, there can be no doubt, has been produced by this belief. It is not at all an unusual thing for me, on taking part in a consultation with the family physician concerning some such case, to be told by him that he very much regretted that he had not made an examination by the speculum. Others have told me that they made the said examination, and when asked what they saw, or what they did, the answers usually given are that they did nothing, they merely made the examination; that is to say, they passed the instrument, and with that proceeding were perfectly satisfied—evidently under the belief that the passage of the speculum was quite as much a curative agent as a method of diagnosis. Similarly with the sound. I have heard many practitioners tell me of their experience with the sound, or rather their want of it, and I judged that they looked upon it as a sort of magical charm, the introduction of which into the uterus was to achieve unmeasured good. As a matter of fact, the sound is one of the most dangerous instruments which ever were invented for the treatment of human suffering, and in my own practice obtains hardly any kind of employment at all.

There is a story which is told against myself by some of my colleagues, which I never hesitate to repeat, because it was the kind of accident which is liable to occur to any one, and fortunately the only one of its kind which ever happened to myself. It conveyed a lesson to me of which at the time I stood much in need, and from which I know thousands of my professional brethren may take warning with advantage. Many years ago I was asked by the surgeon of a large general hospital, with whom I was making a casual visit, to give him my opinion on the case of a young woman who had been in the hospital for some months, suffering from a pelvic tumor which seemed to threaten her life. She had hectic and was suffering and very ill. The tumor on one side of the pelvis was apparently quite fixed, and I gave it as my opinion that it was a collection of matter, but in what position I could not say unless she would allow me to make use of the uterine sound, which, unfortunately for myself, but fortunately for the patient, I had in my coat pocket. My friend told me I could do exactly what I thought proper. He had asked me for my opinion as a specialist, and he would not interfere with any steps I thought fit to take for the purpose of furnishing him with that opinion. I immediately proceeded to use the sound and came, quite erroneously, to the conclusion that the patient was suffering from a parametric abscess.

The sound passed, as I thought, into an empty uterus, fixed toward the right side, the uterus being of the normal length. Within twenty-four hours the patient miscarried of a fourth month pregnancy, and this ended all her sufferings. She speedily recovered and left the hospital, cured in a way which nobody expected, and which certainly I did not intend. All such accidents have by no means so happy an ending as mine had, and their number is immense.

But few months pass without my hearing of a case in which some kind of mischief has not been done in this way. The misuse of these instruments, of course, is due very much to the way in which gynecology has been taught, or rather not taught, in the medical schools of Great Britain. It is unfortunately a subject which is extremely difficult to teach, and therefore has hardly been taught at all. In the first place the classes are too large, and to teach individual students, one after another, is a task which hardly any teacher would care to undertake, and certainly one to which very few of the patients in the clientèle would be brought to submit.

One of the most important methods of diagnosis in abdominal disease, and the first to be considered in examining any case, is inspection, and concerning this method a very great deal of nonsense has been talked. For example, Sir Spencer Wells has told us that inspection will reveal the presence or absence of adhesions; but in my own belief, and certainly from the experience of cases in which Sir Spencer Wells himself has made the diagnosis, there is no possibility of determining by inspection, or any other method, the presence of adhesions anywhere in the case of an abdominal tumor.

A careful examination, by the eye, of the contour of an abdomen, when the patient is lying on her back, with the walls of the abdomen perfectly flaccid, will reveal a good deal to the experienced practitioner. A completely and uniformly distended abdomen may mean that the patient is suffering from peritonitis, intestinal obstruction, ascitic effusion, a parovarian tumor, an ovarian tumor, a large myoma of the uterus, or pregnancy. The process of discriminating between these various conditions may very rapidly be completed by one who is accustomed to dealing with them. Thus peritonitis may be at once detected or eliminated by the presence or absence of the short and rapid pectoral breathing, which shows that the patient is loth to use her diaphragm. In fact, by this alone, and without almost any further inquiry, I have satisfied myself as to the nature of the case by a single glance. Ascitic effusion, on the other hand, is revealed at once by the absence of the pectoral breathing, by the greater flattening of the distention, by its tendency to assume a pyriform shape, the broadest diameter just above the pelvis, by the thickening of the walls due to anasarcous effusion, and the presence of white lines in the skin of the flanks.

If the crest of the ilium sticks out under stretched skin, the diagnosis is again almost complete without further inquiry. If, on the other hand, these subsidiary features are absent, and there be a uniform and complete distention, two conditions widely distinct may be suspected. These are parovarian cyst and hydramnios; and here, again, some very curious mistakes have come under my notice, some of which have had very ghastly results. Parovarian cysts after labor sometimes grow with astonishing rapidity. Hydramnios occurs always with twin pregnancies, and generally in unmarried women, who are, of course, disposed to conceal their unfortunate condition, and mere inspection cannot be depended on to discriminate these cases. But inspection will help us very largely to detect pregnancy and myoma, for in these cases the distention is always greatest either at the middle of the tumor or at its upper part, differing in this way completely from ascitic distentions; and here one of the most important agents in the diagnosis of abdominal diseases, palpation, comes at once to our assistance, and to the skilled fingers it ought not to take more than a few seconds to discriminate between all and any of these conditions. The percussion note, which is uniform in a case of peritonitis, will easily determine the condition which is present. One or two delicate touches of the fingers of one hand, while the fingers of the other lie with the most gentle lightness on the other side of the abdomen, will determine the presence of fluid, and it is in this method of palpation where the fingers of the skilled practitioner at once become visible. The inexperienced hands press firmly upon the walls, and may be seen to move to and fro in an aimless fashion, as if they intended to rock a cradle. The gentlest and tenderest touch alone will reveal what is required. A few trials of the different diameters of the abdomen will teach in as many seconds the leading features which are present: first, that there is fluid; secondly, that it is, or is not, near the surface, being contained, or not so contained, within a thin-walled cyst; thirdly, it is one cavity or not; fourthly, the probable character which it presents. The wave excited by gentle tapping is retarded or urged on by the more or less gelatinous nature of the fluid. All these conclusions can be indicated with the utmost rapidity to the skilled fingers, and it is absolutely impossible to teach how this can be, save by the constant practice of the pupil. The parovarian cyst may be diagnosed entirely from one condition—that is, hydramnios; and partly by the thin walls, and partly by the presence of hydramnios, to which I have alluded, is very easily detected. Ascitic fluid is revealed in the same way, with the additional fact that here and there we get tympanitic percussion notes.

The large uterine myoma is defined by its firm sense of resistance, and its uniformly full and pseudo-fluctuation; also by the fact that it has a smaller diameter at the base than it has at the middle or upper part. Pregnancy, the rock ahead to inexperienced practitioners, can be infallibly revealed by palpation. First of all there is fluctuation due to the liquor amnii, and it can be easily detected, and this declares the cystic nature of the mass. If the hand be made to lie gently on the parietes for a few minutes, a rythmical contraction of the uterus, by which at one time it is hard as a cricket-ball, and at another soft as a cushion, will become perfectly apparent; and this is an infinitely more certain sign than the fœtal heart, or the sound of the placental bruit. The fœtal heart is a sound which may guide and sustain the practitioner in his conclusions, but it is so easily imitated by intestinal noises, and so difficult often to find, that it is not to be depended upon with perfect certainty. The placental souffle is probably more certain than the fœtal sounds, but placental sounds are very often, in rapidly growing tumors of the uterus, so completely imitated that there is always a certain amount of doubt connected with them; but the relaxation and contraciton of the uterus in pregnancy is a method of diagnosis which, when once made apparent, can never be mistaken for anything else.

In all these details the rapidity with which the practitioner will come to his conclusions will depend, of course, in the first place, upon the average rapidity of all his mental acts; secondly, upon the greater or less frequency with which he is called upon to make examinations involving these details; and, thirdly, as I have pointed out, whether he be retarded in his purpose by the obligations upon him to teach others. I feel, in analyzing my own actions in this matter, that they become so habitual to me that I record my conclusions almost without considering in detail the steps by which I arrived at them, and therefore it is not with surprise I now see that my friend, Dr. Vander Veer, has had some kind of justification in his statement that "Apparently I gave but little time for the general examination of patients." But perhaps it is more in the examination of the pelvis, as I have already said, than in anything else, that this apparent rapidity becomes evident, and in striking contrast it stands out with the prolonged time employed for in-

frequent methods of examination, such as in the stethoscopic investigation of the abdominal walls for the finding of the fœtal heart.

I have, as Dr. Vander Veer has quite truly said, an unbounded confidence in the performance of abdominal sections, and I have argued again and again for the extended frequency of exploratory incisions for the purpose of securing complete accuracy of diagnosis; but, and this must never be forgotten, only on the grounds that with the completion of the diagnosis in this way there is at the same time opened out the only road for successful after-treatment. But I must ask that no one who has followed the course of my work will dream for a moment that I pass on the latest side in a difficulty of complete diagnosis to the early side of the issue by its completion in the performance of a laparotomy. To those who are opposed to my views in this matter, of course, nothing is easier than to argue, by means of a charge of recklessness, against my new doctrine. But that such a charge is not to be justified, my results can very speedily determine. That a complete and satisfactory diagnosis can ever be made, save in the simplest condition of disease of the abdomen, without an exploratory incision, I have repeatedly denied. I have said over and over again that the abdomen is a region of darkness, and the man who is most sure about his diagnosis is the man who will be most frequently in error. But this does not mean, nor has one word which I have ever written been intended to mean, that every method that is possible for a correct estimate of the nature of the disease should not be exhausted before the abdomen is opened, either for the purpose of diagnosis or treatment, or both combined. Unless this doctrine be most carefully observed mistakes of the most ghastly and fatal kind will inevitably arise, and they will arise in two conditions clearly, from which, I am proud to say, my own practice is absolutely clear. The conditions of pregnancy are such as to make it perfectly certain that to the reckless operator they will yield an unfortunate harvest. Women who are pregnant when they ought not to be so persistently do their utmost to lead practitioners astray, and the reckless surgeon who opens the abdomen, without having carefully exhausted all methods of diagnosis before coming to the last resource, is certain to be led into the error of opening the abdomen to find a pregnancy in the uterus. This has never happened to me. There will also occur to the reckless surgeon, some time or other, that most mysterious and troublesome of all diseases for diagnostic purposes, to which I have already alluded, hydramnios, due to the over-secretion of the liquor amnii. Seven cases of this disease have passed through my hands, and have been accurately diagnosed in every instance and successfully treated, and I cannot imagine anything much more certain to be a trap for the rash and unwary than this most curious disease. The fact that every one of my cases has been recognized, and properly and successfully dealt with, is an evidence that what I am pleading for is correct.

If I may, in conclusion, take one more illustration to show how completely the results of daily practice, or what may be called rule of thumb, may triumph over the mere teaching of the schools, I would mention the much-discussed bimanual method of examination. I read recently a long rigmarole of nonsense by a German, who evolved from his superabundant inner consciousness, but not from clinical experience, the conclusion that no man could properly examine the pelvis in this way unless he had the patient on her back, turned in the lithotomy position, he being placed opposite the perineum. In the first place, English women would not submit to such brutality, and it is wholly unnecessary. The most complete and satisfactory examination of any woman's pelvis can be made while the patient lies quietly on her left side in bed, without the exposure of one square inch of her skin. Any man who requires more than this is either a pupil or a dullard.

So it is with such a special instrument as Sims' speculum. I have heard some of my American friends say that it is impossible to do any operation upon the vagina satisfactorily without it. All I can say is that I have now cured some three hundred cases of vesico-vaginal and recto-vaginal fistulæ, never having failed in any case, nor having ever refused one, and I habitually pass the sutures with my finger-tips, wholly unaided by speculum of any kind.

This may seem all very boastful to many, but my dear friend, Dr. Vander Veer, has drawn me into it. It may also seem incredible, but it is all true, and can be testified to by many men whose names are household words in the great land west of the Atlantic.

THE INFLUENCE OF CHRONIC BRIGHT'S DISEASE ON THE SAFETY OF ANÆSTHETICS.[1]

By WESLEY M. CARPENTER, M.D.,

NEW YORK.

The condition of the heart has been regarded as the most important factor in estimating the safety of an anæsthetic. This belief has been attested so frequently that it doubtless will remain undisturbed. Whenever an alarming or a fatal collapse occurs with the inhalation of either chloroform or sulphuric ether, or ensues upon the administration of these agents for anæsthetic purposes, the physician turns, almost instinctively, toward the heart for the explanation of the sudden suspension of animation, or the more gradual development of the fatal result.

Preparatory to the performance of a surgical operation, it is the rule, which should never be overlooked, and which has been observed quite uniformly, to examine the heart before administering the anæsthetic.

It is not improbable that this rule had its origin in observations made concerning the effect produced by chloroform, and here it is, doubtless, that it has had its most faithful observance.

The use of sulphuric ether, however, has become so common in this country, and it has been regarded as so safe that, practically, the examination of the patient with regard to the question of safety of administering it for anæsthetic purposes has been very meagre, and by very many the precaution has been omitted entirely.

That it is by far, very far, the safest agent, and at the same time efficient, that can be used generally for producing anæsthesia for surgical operations, is too well established to need special argument to sustain the claim.

The object of this paper is simply to emphasize a pre caution to which attention has already been directed, namely—that the existence of chronic Bright's disease diminishes the safety of the patient to whom sulphuric ether is administered as an anæsthetic.

Surgeons have long recognized that chronic renal disease materially influences the *results* of operations, and to such an extent that every well-informed surgeon approaches with very great apprehension all operations which become necessities in patients whose urine has persistently contained albumen and casts. Sir James Paget has said, and to this Dr. Norris has referred—"Never perform an operation, except under something like compulsion, on a patient whose urine is constantly albuminous."

But the same attention has not been given to the question of the influence which chronic renal disease exerts on the *safety of administering anæsthetics*, especially sulphuric ether.

The literature of this subject is scant. Dr. Turnbull, of Philadelphia ("Trans. Amer. Med. Assn.," 1880), writes with special reference to the *immediate* effects produced, and says, perhaps a little dogmatically, that "it is now a

[1] Read before the Section on Surgery of the New York Academy of Medicine, January 14, 1886.

well-recognized condition that in disease of the kidneys anæsthesia almost invariably produces coma and death."

The chief paper which I have found is that written by Dr. William F. Norris, of Philadelphia, and read before the American Ophthalmological Society at its annual meeting, in 1881, and entitled, "The Administration of Anæsthetics in Bright's Disease of the Kidneys." Dr. Norris reports two cases of death supervening after cataract operations, and they had four features in common: 1. Both patients were anæsthetized with sulphuric ether. 2. They entirely recovered consciousness. 3. They died comatose, one a few hours and the other eighteen days after the operation. 4. In both cases careful autopsies revealed no organic lesion except Bright's disease of the kidneys. He says, "In my opinion both deaths were due to the same cause, namely, the congestion caused in already diseased kidneys by the administration of ether."

The first case was one of congenital cataract. Two hours after the operation the child had a convulsion, and died comatose two hours later.

The second case was one of senile cataract in a woman sixty-eight years of age. The operation was performed in the afternoon; during the evening of the same day her urine diminished in quantity, and was loaded with urates. The urine continued to show varying conditions of abnormality until the seventeenth day, when a small quantity of albumen was detected and fatty and granular casts; specific gravity, 1.008. The patient died the following day

In both cases a microscopical examination of the kidneys revealed intense congestion with parenchymatous and fatty degeneration. This condition of the kidneys was also present in a case referred to by Dr. Norris, and reported by Dr. Hunt, of Philadelphia (Philadelphia *Medical Times*, January 9, 1875), namely, a marked state of fatty degeneration, and the writer asks the significant question, "May not conditions of this kind often explain the unpleasant, and even fatal, action of an anæsthetic?"

Commenting on Dr. Turnbull's paper and on the reported cases, Dr. Norris says: "If the administration of ether can, in certain cases, so stimulate some latent form of chronic Bright's disease as to cause decided interference with the function of the kidneys, and death from uræmia, at an interval varying from some hours to two or three weeks after the operation, we have certainly additional and grave cause well to weigh the propriety of administering anæsthetics in all operations for chronic diseases in persons with albuminuria, and certainly ought never to perform one without examining the urine."

"I am well aware that anæsthetics are frequently administered in puerperal convulsions, and that ether is occasionally given in cases in which the patients are known to have Bright's disease, and without apparent evil results; but, because fatal results do not follow in all cases, we have no right to shut our eyes to those where their employment apparently leads to fatal disturbance of the renal function."

I now wish to add two cases to those which have been reported.

Case I.—On November 24, 1885, I superintended the post-mortem examination made on the body of a middle-aged woman who had been operated upon for recto-vaginal fistula in one of the large hospitals in this city. I was also told by one of the house staff that the patient had been in the hospital for some time, and that at the occasional examinations a small quantity of albumin had been found in her urine. She desired an operation, as life, with her infirmity, was well-nigh intolerable. Ether was administered with the precautions usually observed in large hospitals, and the patient, without special warning, died upon the table just before the operation was completed. Only a small quantity of blood was lost.

Autopsy twenty-four hours after death. The *heart*: The left ventricle was contracted, its wall hypertrophied, its cavity empty, and its valves normal. The wall of the right ventricle was relaxed, its cavity was empty, and the valves were normal. Microscopical examination of the muscular fibres revealed that they were substantially normal, only occasional pigment granules being present.

A small quantity of dark-colored watery fluid could be pressed from the cut surface of the lungs; the bronchial tubes contained a small quantity of reddish frothy fluid, and the trachea and larynx were unobstructed.

The liver was enlarged and fatty. The spleen was increased in size and was dark-colored.

The prominent lesions were found in the *kidneys*, which were increased in size, the capsules were adherent, the cortices were thickened and pale, and the pyramids were of a deep red color; the pelves and the ureters were normal. Microscopically, they showed the lesions of chronic diffuse nephritis; the intertubular connective tissue was increased, the capsules of the glomeruli were thickened, the tubules were either empty or contained swollen and granular, or broken down and fatty epithelia and casts; the blood-vessels were distended with blood.

The uterus was normal; the left Fallopian tube was dilated, and the left ovary contained a small cyst. There were old pelvic adhesions. The notable features of this case were: (1) the persistent, though slight, albuminuria; (2) the administration of ether; (3) the sudden death; and (4) the marked lesions of chronic Bright's disease with evidence of an acute process.

In estimating the cause of death in such cases, the fact must not be overlooked that all surgical operations, as a rule, are attended by more or less of shock, varying in degree from the slight and transient to the profound, from which the patient never rallies. But here the surgical procedure did not belong to the class regarded as severe operations, and the loss of blood was what is usually regarded as insignificant.

These remarks, so far as shock and loss of blood are concerned, are applicable to the next case.

Case II.—On January 1, 1886, I was invited to examine the organs removed from the body of a middle-aged, powerfully built man, who had died eight hours after the administration of ether and the performance of what is regarded by surgeons as essentially a safe operation, and with the loss of only a moderate quantity of blood.

Two weeks previously this man had been operated upon under the influence of ether, and had, within the usual length of time, passed from under the influence of the anæsthetic without the appearance of any unfavorable symptoms.

After the second operation he apparently rallied completely from the ether, and felt comfortable in bed. At the end of eight hours he got up, went to the water-closet, returned to his bed, was soon heard breathing peculiarly by the other patients, who gave an alarm, but before any medical attendant could reach his bedside he was dead.

The autopsy was performed thirty-six hours after death. Nothing abnormal was found in the brain, except an atheromatous condition of the arteries at the base, a small clot in one of the sinuses, and marked venous engorgement.

The *heart* weighed twenty-four ounces. There were marked hypertrophy and dilatation of the left ventricle. The mitral valve was incompetent (the orifice admitted three fingers) and there were atheromatous patches about its base. The aortic valves were competent; one cusp exhibited a small vegetation upon the ventricular surface. The wall of the right ventricle was very thin, having been encroached upon to such an extent by fat that the muscular tissue was reduced to about one-sixteenth of an inch in thickness. The pulmonary and tricuspid valves were competent. The aorta was markedly atheromatous. Microscopical examination of the cardiac muscle showed the fibres to be normal.

The liver was increased in size; was firm and red Microscopical examination showed that it was slightly cirrhotic, and also the seat of a moderate amount of fatty infiltration. The blood-vessels were filled with blood.

The *kidneys* weighed nine ounces each. The cortical portion was thick and pale; the pyramids were deep red; the capsule was thickened and markedly adherent.

The spleen was enlarged and firm. Microscopical examination of the kidneys showed the lesions of chronic diffuse nephritis, with marked congestion of the blood-vessels of the pyramids, and a swollen and fatty condition of what epithelia still remained in the tubules. Many of the tubules contained casts.

It will be seen at once that in this case there existed a complex condition of things. There was chronic disease of the heart and chronic Bright's disease. The cardiac disease, also, was of the character which favors the supervention of a sudden fatal result on subjecting the patient to any one of several causes.

The kidneys, however, showed the same appearances microscopically as do many kidneys which are the seat of chronic Bright's disease occurring *unassociated* with chronic cardiac disease, and to these were added the vascular and parenchymatous changes belonging to an *acute process;* possibly this acute process was produced by the anæsthetic.

As evidence that this is not an unreasonable conclusion concerning the possible effect produced by the ether, I will refer to a paper read by M. Lafont, at a recent meeting of the Société de Biologie, Paris, in which he makes special reference to the secondary effects of nitrous oxide as an anæsthetic; second in order of mention "is the appearance of albuminuria in a certain number of patients suffering from cardiac disease." [THE MEDICAL RECORD, January 9, 1886.]

Gynecologists have turned their attention in this direction, and from time to time, in their discussions in this country, especially in the American Gynecological Society, reference has been made to the importance of fully appreciating the condition of the kidneys in connection with all operations and the use of anæsthetics. Dr. T. A. Emmet has been so impressed with the importance of this question that he has directed special attention to it in his work on gynecology, in the significant words, "I called the attention of the profession to the greater necessity of examining the condition of the kidneys than that of the heart." "Since then I have had at least *five* deaths occur from uræmic poisoning, which, perhaps, might not have occurred if my assistants had been able to examine, or had appreciated the importance of examining, the urine *before the anæsthetic was given.*" (Italics mine.)

From the foregoing I have been led to the following conclusions:

1. Too great care cannot be exercised in examining the urine, both chemically and microscopically, of all patients who are to undergo surgical operations.

2. Chronic Bright's disease diminishes the safety of anæsthetics, especially sulphuric ether, as well as the safety of the operation.

PARENCHYMATOUS NEPHRITIS CONSECUTIVE TO VARICELLA.—Dr. Franz Hogge reports several cases in which the causal relation of varicella to parenchymatous nephritis was apparently indisputable, and deduces from the study of these cases the following conclusions: 1. Secondary renal inflammation may follow an attack of varicella as well as those of other infectious diseases. 2. Notwithstanding the benign character of varicella, the consecutive nephritis may be as intense as that following scarlet fever, measles, or small-pox. 3. The symptoms of nephritis may become apparent in from five to twenty-one days subsequent to the attack of varicella; they have never been observed during the course of the exanthem or before the desiccation of the vesicles.—*La France Médicale*, December 15, 1885.

DIAGNOSIS AND TREATMENT OF INTRA-PERITONEAL WOUNDS OF THE URINARY BLADDER.[1]

BY ALEXANDER W. STEIN, M.D.,

NEW YORK.

MR. CHAIRMAN AND FELLOWS OF THE SURGICAL SECTION: It seems to me you could scarcely have chosen a subject more deserving our joint consideration than the one now before us, for intra-peritoneal injuries of the bladder are not of such frequent occurrence as to enable us individually to acquire a large experience with them, and yet the gravity of the lesion is such that it demands of us an early recognition and a prompt and judicious surgical interference. Intra-peritoneal injuries of the bladder have thus far almost invariably proved fatal. I have not found a single instance of recovery after urinary extravasation from either gunshot, incised, or punctured wound of portions of bladder invested by peritoneum, although at least twenty-eight cases of the former, and thirteen of the latter, have been collected. Juillard[2] and Homans[3] both accidentally opened the posterior wall of the bladder during ovariotomy. Fortunately, there was no extravasation, and both women recovered. Of the nearly two hundred cases of intra-peritoneal lacerations recorded, five have been claimed as instances of recovery, by Chaldicott, Thorp, Walters, Mason, and McDougall, respectively. Of these, however, Walters' patient is the only unequivocal instance of recovery. Here laparotomy demonstrated the existence of an intra-peritoneal laceration two inches in length. That the other cases were intra-peritoneal, is merely a supposition, based mainly on two facts: First, (Thorp's case), that the beak of the catheter passed through the rent beyond the bladder and removed urine, and second, the occurrence in all cases of peritonitis. In regard to Thorp's case there is every reason to believe that the catheter did not actually enter the cavity of the peritoneum, but passed into a sub-peritoneal pouch. Neither can the existence of peritonitis be regarded as a conclusive evidence of the involvement of the peritoneum in the injury. There is hardly anything in the history of Chaldicott's patient, other than the existence of peritonitis, that would lead to the belief that it was an instance of intra-peritoneal laceration, nor is there anything more conclusive in the other cases cited.

After intra-peritoneal stab and punctured wounds death invariably occurred by the third day. In the corresponding gunshot wounds more than one-half the subjects survived the second half of the first week. About one-half the intra-peritoneal lacerations terminate fatally within three days. Few survive the first week.

That by far the largest number of vesical lacerations are intra-peritoneal, finds its explanation probably in the fact that when the bladder is distended and is subjected to violent or sudden compression, the peritoneum, which is then the most tense and least yielding of the several tunics, will split in advance of the subjacent coats and carry the latter with it in the laceration. Most frequently the rupture occurs at the upper and posterior part of the bladder, where the viscus is thinnest, and where in the course of distention it comes in relationship with the vertebro-sacral promontory, against which it is forced. Atony, ulceration, and tunicary herniæ of the vesical walls have naturally enough proved predisposing causes of rupture, but in the vast majority of cases the coats of the bladder were healthy at the time of the injury.

One would expect that a degree of thickness or hypertrophy of the vesical walls would be a safeguard against rupture, but a specimen in my cabinet shows extensive laceration through a contracted bladder whose walls are three-fourths of an inch thick. This man had long suffered with stricture. A kick on the abdomen caused the laceration. A more or less replete state of the bladder

[1] Read before the Surgical Section of the New York Academy of Medicine, January 11, 1886.

[2] Arch. f. klin. Chir., Berlin, Bd. xxv, No. 2.

[3] Boston Med. and Surg. Journ., February 18, 1882.

usually exists previous to the accident, but complete vesical distention is not a *conditio sine qua non*. Rupture by *contre-coup*, as in falling from an elevation upon the feet or buttocks, has occurred even when the bladder was comparatively empty. Wernher's patient passed water half an hour before this accident occurred. That external violence over the region of the viscus is by far the most common determining cause, is well known, but perhaps we do not equally keep in mind that the force may emanate from the individual himself, as occasioned by straining in micturition, etc. Thus, stricture and enlarged prostate have proved factors in the causation of this injury. The bladder has been ruptured during parturition. *A warning to the accoucheur to secure the evacuation of the viscus during labor.* It has occurred from retention of urine induced by the retroverted gravid uterus. In several instances the rupture seems to have been caused solely from pressure of the abdominal muscles upon the distended bladder, without any obstacle to the escape of urine or diseased condition of the bladder-walls being apparent. A man with retention, laceration of the urethra, and extravasation of urine sustained a rupture of bladder in his struggles while undergoing etherization in Bellevue Hospital. *A warning not to administer anæsthetics while the bladder is in a condition of distention.*

The symptoms of our lesion are usually as follows: Inability to walk or stand; severe pain over hypogastrium; incessant desire to micturate, with an inability to void the smallest quantity of urine, or possibly but a few drops mixed with blood; constitutional symptoms indicative of great prostration rapidly ensue, coma or convulsions supervene, and death comes to the relief generally in a few hours, or, at the furthest, a few days. If the subject rallies from this shock or collapse his life is next imperilled by the development of peritonitis or septicæmia. As to the significance of peritonitis as an element in diagnosis between intra- and extra-peritoneal lacerations, it is nothing more than strongly suggestive of the former. Peritonitis in a given case does not necessarily denote laceration of the peritoneum; it is often associated with extra-peritoneal ruptures, either as the direct result of traumatism independent of injury to the bladder, or as the consequence of extension of inflammation from neighboring parts. Of great diagnostic value is the statement so often made by the patient that after the blow over the hypogastrium, or while in the act of straining, he "felt something give way within the abdomen," or "experienced a sudden relief from the discomfort occasioned by the previously distended bladder." The evidence furnished by catheterization is of special value when it is positively known that the individual had not micturated for several hours previous to the accident. Under these circumstances an empty bladder, or one containing but a small quantity of sanguinolent urine, is strongly confirmatory of laceration. Nevertheless, it must be admitted that evidence pointing to this injury is by no means always unequivocal; often the signs and symptoms upon which we would most rely are absent, and those that exist are dangerously misleading, and the case is shrouded in uncertainty and doubt. We depend much upon the statement made as to the nature of the accident, the condition of bladder at the time of injury, relative to distention, etc., but if the patient is unconscious, or is drunk, as is so often the case, no information can be obtained, or what may be given cannot be relied on

If we will take a lesson regarding the inconstancy and unreliability of the most characteristic symptoms, we shall find that standing, or even walking some distance, is not inconsistent with the existence of laceration of the bladder. Neither is the difficulty or inability to micturate a uniform symptom. The patient may have no difficulty in voiding urine, and, indeed, may pass a considerable quantity of water. Gruber's patient, with an intra-peritoneal laceration one and a half inches long at the summit of bladder, "was able to pass water without any difficulty." He died eighty hours after the injury. In some instances quite an interval of time elapsed between the receipt of injury and the development of characteristic symptoms. This would seem explicable only on the supposition that at first the rupture was incomplete, and it should teach us to watch closely a patient on whom the suspicion of rupture rests, for, though the symptoms may for a time be latent, once manifest, they are rapidly progressive.

The retentive power of the bladder noted in some cases was remarkable, and was accounted for in the closure of the vesical wound by "valvular protrusions" and "adhesions." A man fell, and manifested symptoms which led to the diagnosis of laceration of intestine. The catheter evacuated a *large quantity of perfectly clear urine*. He died in twenty-four hours, and the autopsy revealed a large tear in the bladder, into which a coil of intestine had slipped and become engaged. The intestine was found uninjured. There were signs of general peritonitis, and a large quantity of urinous fluid was found in the cavity of the peritoneum. Several other instances might be cited to show that the presence of clear urine in the bladder cannot be accepted as absolute evidence against the existence of injury to this viscus. On the other hand, we should know that the sudden advent of blood in the urine is nothing more than a presumptive evidence, strong though it may be, of this lesion. The urine may be tinged with blood from simple contusion of the bladder without laceration. A man was stamped upon and thrown down-stairs; he was brought to the hospital in a state of profound collapse. There were signs of injury over the abdomen. A catheter withdrew a quantity of *dark, bloody* urine. The entire appearance of the case led to the diagnosis of rupture of the bladder. He died in ten hours, and the autopsy revealed a laceration of the ilium and *no injury* to the bladder. Then, again, if, in addition to the appearance of blood, there should be diminution or, perhaps, suppression of urine, a condition not infrequently concomitant with shock following serious internal injuries, we should meet with additional embarrassment in our diagnosis. In eight or nine instances the diagnosis of rupture was established by the accidental passage of the catheter through the vesical rent into the abdominal cavity. If, after entering the bladder and removing, perhaps, a few drops of urine, the catheter is suddenly felt to slip into a secondary cavity, in which its beak is freely movable, and from which a considerable quantity of sanguinolent urine escapes, it is probable that the laceration extends into the peritoneal cavity, but the instrument may have entered either a sub-peritoneal pouch, or, if the rent is situated low enough, may have passed into an extra-peritoneal circumscribed collection of urine. In some cases a most characteristic sign was noted: That warm water injected through the catheter was felt by the patient in the abdomen, and the escape of the fluid ebbed and flowed with the respiratory movements.

The foregoing facts must certainly tend to disturb our faith in symptoms, and well they may, if in appreciation of their unreliability we shall be led *without delay* to seek the more positive information which digital exploration will yield. In the female this may be readily accomplished through the short urethra. In the male the same may be effected by means of a small, median, perineal incision. If the question still rests between intra- and extra-peritoneal laceration, a supra-pubic incision will dissipate all doubt, at first carefully avoiding the peritoneum. Should the injury prove to be without the peritoneum, the supra-pubic incision will have done no harm. On the contrary should it be intra-peritoneal, it will have been the initial step to a laparotomy.

Intra-peritoneal lacerations have been treated by catheterization, paracentesis, cystotomy, and laparotomy. Paracentesis of the recto-vesical cul-de-sac has been frequently suggested on the supposition that the extra-

vasated urine will gravitate and accumulate at the most dependent parts of the peritoneal cavity, but, in reality, such is not the fact; the urine, when it escapes, is diffused over the entire abdominal cavity by the peristaltic movements of the intestine and by the suction action of the diaphragm, and will not accumulate at one point unless incapsuled by peritoneal agglutinations. When such is the case, and a distinct fluctuating tumor is recognized per rectum, it should be evacuated and the cavity washed out. Several writers mention the existence of such collections of fluid, but it does not appear that any attempt was made to puncture or aspirate those collections in any of the cases.

Lateral cystotomy has been practised several times, but as it cannot accomplish anything toward the removal of urine and blood from the peritoneal cavity, I do not see that it is suggestive of benefit, except as a means of effecting bladder drainage, and for that purpose the catheter *à de meure*, by Chiene's method, with steady and gentle aspiration, is all that could be desired, and, unlike cystotomy, does not entail an additional danger to life.

The advantages of laparotomy, in intra-peritoneal injuries, are: 1, That it permits direct inspection of the seat of lesion and the appreciation of concomitant injury to other parts; 2, that it permits of the removal from the peritoneal cavity of the extravasated urine and blood; 3, that it permits of the cleansing and disinfection of the peritoneal cavity; 4, that it permits the accurate closure of the vesical wound, preventing further effusion of urine. These are undoubtedly the indications to be fulfilled, and the more successfully they are met, the greater the chances of recovery from an otherwise fatal injury. Abdominal surgery has long since established the fact that the danger to life is not in the laparotomy, but in the presence within the peritoneal cavity of a decomposable and septic fluid, and when this is removed shortly after such extravasation has occurred, laparotomy may be practised with every hope of success. This statement receives additional confirmation in the experiences of Juillard and Homans. These gentlemen both injured the intra-peritoneal portion of the bladder during ovariotomy. Fortunately, the bladder was empty, so that no urine escaped into the peritoneal cavity, and both patients recovered. In the first instance, a wound four and one-half inches long was closed with fifteen catgut sutures. Catheter was retained six days; the following four days bladder was catheterized every two hours. After tenth day, urine was voided without catheter.

In the second patient the wound two inches long was brought together by a continuous carbolized silk suture; on the tenth day catheter was removed.

Laparotomy has been performed four times by Walter (1859), Willett (1876), Heath (1876), and Bull (1884). If we ask what encouragement these cases hold out for a repetition of the operation, we find that but one of the four proved successful, that of Walter's. Yet, if we examine into the causes of failure in the other cases, we find that the factors that operated against their success may hereafter be avoided. Walter's successful case was operated on only ten hours after the accident, while Willett operated thirty hours, and Heath forty-two and a half hours, after the injury, both the latter cases being pretty well advanced in dangerous symptoms before the operation was undertaken. In the fatal cases there was imperfect closure of the vesical wound. In the case of Willett the edges of the wound were not closed even at the time of the operation, and in Heath's case, in which a continuous suture was used, the knot slipped or gave way a few days afterward. I think, therefore, it must be admitted that with this experience behind us we have no reason to lose confidence in laparotomy. On the contrary, we should feel encouraged to give it further trial.

The ends to be attained are, thorough cleansing of the peritoneal cavity and the accurate closure of the vesical wound. True, Walter was successful with the wound two inches in extent left open, and it serves to show to what extent the catheter may be relied on for purposes of drainage against the suggestion of perineal cystotomy. But I think few will care to follow Walter's example. In the application of sutures the bladder may be made more accessible by distending the rectum with a colpurenter. The stitches should be taken close together, and in a double set, as recommended by Vincent. In one set—the sero-muscular—taking each suture through the peritoneal and muscular coats of the bladder on each side of the wound; in the other set—the sero-serous—taking the peritoneum alone, a considerable width of this coat being included on both sides, so that when these sutures are hid, wide serous surfaces are brought in close contact, as from this surface the most plastic material is exuded. The mucous membrane should not be included in any of the sutures. As to the material used, carbolized silk (Homans). and catgut (Juillard), have both proved faithful to the trust. If the edges of the wound are much damaged or very ragged they may be vivified before the sutures are applied, but usually this will be unnecessary. Before the abdominal wound is closed the accurate coaptation of the vesical wound should be tested by moderately distending the bladder with water or milk, and if there be any escape between the sutures, an additional stitch applied.

Whether a small drainage-tube of sufficient length to reach to the bottom of the pelvis should be secured at the lower angle of the abdominal wound, is a question. Mr. Heath believes that in his case it not only did not serve the purpose for which it was inserted, but actually caused and intensified peritoneal inflammation. Finally, a catheter should be retained in the bladder with constant and gentle aspiration, or, if preferred, a drainage-tube may be inserted through a small opening into the prostate urethra.

WATER-SUPPLY OF CITIES AND VILLAGES.[1]

By A. VANDER VEER, A.M., M.D.,

ALBANY, N. Y.,

PRESIDENT OF THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

GENTLEMEN: As our "Transactions" will show, for a number of years I have presented several papers on various surgical subjects, and, had I consulted my own inclination, I should again have pursued the same line of thought; but, realizing the great good and influence that our society exerts upon the people as a whole, I have thought best to take up a subject which is now commanding great attention, and must ever continue to do so, while it becomes part of the work allotted to the medical profession.

That all thoughtful members of the human family are ever willing to grant full praise to the worthy divines who have done us so much good, I think there can be no doubt; and that the wise laws, with interpretations given us by eminent jurists, have led us to render great respect to the profession of law is also a recognized truth; yet to neither would I surrender the high and exalted position now occupied by the profession of the healing art in the so-called domain of preventive medicine. The writings of that great man in our profession, who has but recently passed from us—Professor S. D. Gross—are full of the precept-upon-precept teaching and earnest suggestions to the younger men to work in this field of investigation after the causes of disease, for that in it should be found the greatest honor and reward.

In the consideration of this most prominent factor in the cause, production, and spread of disease, water, I know that I am upon ground that has been ably worked by those better prepared by study, and perhaps investigation, than myself, yet I hope in some way to present old and new material in a manner that will work to our mutual instruction and the future good of the different communities in which we move.

[1] Abstract of the Anniversary Address before the Medical Society of the State of New York, at the Twenty-second Annual Meeting, delivered at Albany, February 2, 1886.

We hear it often stated, that in the supplying of pure water to large cities we have not held our own with the ancients. Granting this to be true in the past, I predict that there are those within the reach of my voice who will live to see this assertion thoroughly refuted.

The President then gave a brief outline of the history of obtaining water by wells, which went back to the earliest period of man's existence. The art of boring wells was known about four thousand years ago. After referring to artesian wells, he spoke of *driven wells*, and reached the conclusion that in these wells, put down by the gang method, we have embodied the principle of natural filtration, and that wherever the ground-water is of good quality, and sufficient on trial, of proper depth, and free from possible contamination, it furnishes by far the safest water short of what may be considered nature's purest supply, namely, spring-water.

The applications of the driven-well system for obtaining large volumes of pure water for the supply of a city of six hundred thousand inhabitants is a new departure, and can no longer be considered an important experiment, but an assured success.

As the water obtained by this system comes from depths of forty to one hundred feet below the surface, it is very pure and the supply is steady throughout the year. By other systems the supply is taken from the surface-water, and its quality is often impaired by local impurities, while the quantity in different seasons varies with the rainfall.

The ancients early manifested a desire to procure water from other sources than wells, and by means of aqueducts sought a pure supply even at a great distance from springs, lakes, and mountain sources.

Reference was then made to the aqueduct system as it existed in Egypt and Rome, and at present in India, where it forms a part of the system known to have been employed as far back as the eighth century B.C. The repair and maintenance of these aqueducts became quite expensive, and would be much more so in this country and at the present time.

To every one who is called upon to advise in the question of water-supply, there are certain considerations that must at once claim his careful study and investigation. First to be considered is the quality of the water sought, and no doubt he will, at the present time, have uppermost in his mind the well-known fact that no amount of impure water will cause true cholera and allied diseases, the presence of the microbes being necessary before such waters can do harm in spreading such diseases, although when once there, there is no end to the harm they may do. It is almost hopeless to fight Asiatic cholera with polluted water.

On sanitary grounds soft water is certainly to be preferred; it is true there is no hard water but that can in a manner be softened. One accustomed to drinking soft water should be careful when entering a hard-water section not to drink too freely of the water, and *vice versâ*.

If we consider the quality of water for drinking and domestic purposes, and, that being decided favorable, then at the same time can secure quantity, we have solved the problem for any community.

Beyond a doubt spring-water, as procured from deep springs, or as fed to our mountain lakes, is not only the most palatable but the most wholesome of waters. Next we may rely upon artesian or driven wells, keeping ever in mind the danger of sewage contamination. Large rivers may be made use of, or smaller streams fed by springs and surface-water, but contamination must be guarded against with the greatest care. River-water that has a long distance to run may purify itself from sewage and other forms of pollution, but it, together with water from shallow wells, must be looked upon as dangerous, though it may be pleasant to the taste and sight.

If care be exercised in collecting and storing rain-water, it may be considered safe for drinking and domestic use to a limited extent.

Water, as we are aware, may be clear and sparkling—it may also be palatable—and yet be a disease-spreading water, because of the presence of the germs of typhoid fever, or the microbes of cholera, which no filtration can remove. "The intestinal discharges of typhoid-fever patients, it is well known, contain an infectious agent which has great vitality and enormous power of multiplication and propagation."

One simple fact ought not to lead us into condemning a water-supply, but when we know that certain epidemics have arisen from water-pollution, then we are in duty bound to heed that form of warning, or else suffer that which we might have avoided, and in so doing disgrace the province of preventive medicine.

Now, if we take unpolluted spring-water as our standard, how much may we deviate from it and yet be safe? We must bear in mind that even this source of supply may become contaminated.

Here the President gave an extended review of the late Plymouth epidemic of typhoid fever, and illustrated this part of his subject with elaborate maps.

In the matter of shallow or old wells that have become polluted, public opinion often requires time to crystallize in its exactness or conclusions before sanitary laws can be enforced. The microscopic and biological examination of drinking-water has received a decided impulse in the researches of Koch.

Fortunately, within the past few years biological researches have been conducted with such skill, in the examination of bacteria and microbes, as to largely relieve us of the uncertainty in which the chemists often leave us as to the purity of water. That is, by means of sterilized culture-tubes it is possible to determine as to the amount of disease-germs water may contain.

This method of estimating the potability of waters by the number of living organisms in a given volume has been systematically employed for several years in connection with the sewage irrigation works of Berlin, and the value of the bacterioscopic examination of water has in the last few months been recognized in England.

One great advantage of bacterioscopy over all chemical processes which fail to distinguish between living and dead matter is that it determines the actual number of *living* bacteria in a given volume.

It has long been known that dangerous microscopic animal parasites gain access to the body with the drinking-water.

This is a fact, that water containing an abundance of bacteria contains also enough organic matter to render it unfit for drinking purposes. Fish may thrive at the open end of a sewer that empties *fresh* sewage, but not so if the sewage has become putrid and contains these micro-organisms.

In view of the great difficulty of procuring a sufficient quantity of pure water, and, again, when possible to obtain it, the attendant expense, the question is forced upon us, Can known polluted water be purified?

So far as the answering of this question goes, there are many suggestions offered, but few at all satisfactory. The conclusions of the River Commissioners of Great Britain on this subject are that there is no river in the United Kingdom long enough to secure the oxidation and destruction of any sewage that may be discharged into it, even at its source. While they do not condemn entirely these rivers after an attempt has been made to purify them, yet they do not advise such sources as safe potable waters. These known polluted rivers are often the source of winter diarrhœas, and even more serious consequences, due to the ice-bound condition of the stream preventing the access of oxygen to the water.

Professor Nichols says: "It is certain that we cannot decide with confidence when a stream, once polluted, becomes fit to drink. Moreover, as it is not possible by any practical chemical treatment, or by any process of

filtration, to make a polluted water wholesome, it is safer not to use, as a source of domestic supply, water that is known to have been seriously polluted." We have quoted in this paper the extreme views of two well-known English authorities, but as one reviews the facts carefully he is convinced that a thorough artificial filtration will improve polluted water sufficiently to make it comparatively safe. The method of sand-filtration can be relied upon for the removal of suspended impurities, and it also lessens the amount of organic matter in solution, but the dreadful typhoid-fever germs and like the cannot be reached.

Probably the best material for domestic filters is spongy iron, being superior to animal charcoal; and Bischof, a good authority, lately informs us that filtration through the iron destroys bacterial life, and that water so filtered is incapable of inducing putrefaction in animal matters. Frankland, in his recent investigations, arrives at the same conclusion, and is much in favor of the use of spongy iron for the purification of polluted waters. Then, if polluted water must be used, it should by all means be filtered; and, if there is any suspicion of disease-germs, for domestic purposes it should be boiled from one to two hours, and put in closed earthen or glass vessels in a cool spot for several hours before drinking. The flatness of taste can easily be removed by repeatedly pouring it from one vessel to another until sufficiently aerated. A fresh supply should be prepared every twenty-four hours.

However much it may be deplored, it must be admitted that a large proportion of the waters supplied by public works at the present time require filtration.

The conclusions were that we should, if possible, procure water for domestic uses, first, by gravity and from mountain streams, lakes, or springs; second, the surroundings being safe and proper in every respect, by the gang-syphon driven wells; third, by a system of storage, but so arranging the reservoirs that proper aeration can be employed; and, lastly, if it must be taken from sources known to be polluted, a thorough system of filtration should be employed, and the water as completely oxygenated as is possible before distribution.

Progress of Medical Science.

Hyperthermic Scarlatina.—M. M. Bloch and Vicente report in the *Revue Mensuelle des Maladies de l'Enfance* for October, 1885, the case of a nursing infant, five months old, who was attacked with scarlet fever. The eruption was well marked on the chest and abdomen, scanty over the other parts of the body, and almost entirely wanting on the face. On the third day the temperature rose to 109° F., and the child had convulsions. A lukewarm mustard bath was given, and the body afterward sponged off, while cold compresses were applied to the head. Within an hour the temperature fell to 107.5°, and by evening was down to 103.8°. Four days later it was nearly normal. The child made a good recovery.

The Influence of the Iodides on Nitrogenous Metamorphosis.—The precise way in which the iodides act on the tissues of the body is a subject still involved in obscurity. Their favorable action in various diseased conditions is universally known, but their effects in healthy subjects have received very little attention. Dr. Smirnoff, of St. Petersburg, has undertaken a series of experiments to elucidate the topic in question, especially, however, the influence of the iodides of alkalies on nitrogenous metamorphosis. He directed his attention chiefly to the general nutrition, growth, and development of young animals that received daily iodide of sodium to the amount of two drachms, or iodide of potassium of a little over one drachm. The results obtained by Dr. Smirnoff may be stated as follows: 1. Iodides of alkalies undoubtedly increase disintegration of the proteids of the body; hence an increase of nitrogenous products, as well as of phosphoric and sulphuric acids, is observed; the general systemic nutrition fails, and there appears wasting of the body. 2. Under prolonged use of iodides, the assimilation of nitrogenous elements of the food decreases. 3. The digestive function of the gastric juice fails, though the quantity of the juice remains unchanged. 4. Under prolonged use of iodides there appears albuminuria (on the sixteenth, twenty-sixth, and thirty-second days). 5. Iodine is not eliminated from the body very quickly, as is generally supposed; it may be stored in the system and eliminated only gradually. [In one of the experiments iodine entirely disappeared from the urine only on the fourteenth day afteri ts ingestion; in another, only on the twenty-second.] 6. Iodides of alkalies seem to have no irritant action on the gastro-intestinal mucous membrane. Considering the experimental data above in connection with clinical facts, Dr. Smirnoff comes to the conclusion that a favorable therapeutic action of iodides in syphilis, goître, scrofula, and allied disorders, cannot be explained exclusively and directly by an increase of nitrogenous metamorphosis in consequence of the administration of the drugs; the explanation is to be sought rather in the fact that iodine, being introduced into a diseased system, acts before all and most intensely on morbid products which are less durable and more easily yield to all possible influences than normal tissues of the animal system.

Chorea and Typhoid Fever.—That typhoid fever may abolish chorea is a well-known fact. It does not seem to be so generally known that typhoid fever may originate chorea. Rilliet and Barthez have observed the development of chorea in a patient who was ataxic after typhoid fever. Benedict has also described a tremor of the head with unilateral convulsions. Nothnagel and Ebstein have witnessed choreiform disorders consecutive to pythogenic fever. But if chorea may be regarded as of rare occurrence during convalescence from typhoid fever, it is extremely rare during the actual course of typhoid fever. Peiper has recorded the case of a girl, aged sixteen, who was attacked with typhoid fever, from the first commencement of which involuntary movements of a foot were observed. On the ninth day, however, chorea was fully established, apparently as the result of a violent emotion caused by the receipt of the news that her mother had just died from enteric fever. From the description, it would appear that the chorea was general and severe. It lasted altogether ten days, and during the whole time considerable pyrexia was present. The fever ran a normal course, and convalescence ensued naturally. There was a systolic murmur of obscure character, which finally disappeared. The dependence of the chorea on the cardiac lesion was regarded as out of the question.—*The Lancet.*

Idiopathic Pneumothorax.—Dr. Desmaroux reports the case of a young and exceptionally strong man, who had never been sick, and in whose family there was no history of tuberculosis, who was taken suddenly, while walking, with repeated chills and a very severe pain under the right breast. There was a feeling of great oppression in the chest, and the man staggered in walking, and was obliged to sit down every few minutes to rest himself. Examination showed a bulging of the right side of the chest, and percussion gave a tympanitic resonance, while a feeling of elasticity in the thoracic wall was imparted to the percussing finger. There was complete absence of the normal respiratory murmur, which was replaced by a characteristic amphoric blowing sound. Coughing was performed with difficulty and was without expectoration. Three days after the disease, the patient became delirious, and died. The author believed that this was a case of pneumothorax due to an excretion of gas from the pleura, and not caused by rupture of a healthy lung.—*Centralblatt für Klinische Medicin*, December 5, 1885.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 6, 1886.

STATE REGULATION OF THE PRACTICE OF MEDICINE.

UNDER this title, Dr. William C. Dabney discusses, in *The Physician's Magazine*, the present aspect of the subject indicated, and gives some of the results which have been reached by the Virginia State Board of Examiners, of which body he is the president. He discusses, first of all, the desirability of such laws in their application both to the protection and welfare of the community, and to the general subject of raising the standard of medical education. Not content with general reasoning, he adduces some very definite facts brought to light by this State Board. There have thus far appeared before it thirty-nine candidates. All but two of these were graduates of reputable colleges situated in various parts of the country. Of this entire number, eight were rejected. The answers given by some of the candidates to questions on professional topics were certainly unique, and we cannot forbear mentioning a few of them. For the chemical name of common salt, "bicarbonate of soda" was given. The indications for treatment in cholera morbus were considered to be, first, the quieting of the pain, and secondly, removal of the irritant by "*the stomach-pump.*" The vexed question of the preferable way of treating diphtheria was settled by one man to his own satisfaction, at least. It was "belladonna, argenti nitras, aqua calcis, and prophylactics." Apoplexy was defined as a "congestion of the brain, coming on at different times." One man (evidently not a lover of Izaak Walton) mentioned among the causes of hip disease, "taking cold sitting on damp ground; sitting on the banks of rivers, fishing." The centres for will, memory, etc., were located by one candidate in the "spinal marrow." In what light he regarded the cerebrum is not stated. The climax was capped, however, by the answer to the question for an account of the method for ligating the subclavian artery. The candidate advised the Fabian policy that "the patient should be kept quiet and watched clost."

We learn that twenty-nine States and Territories have passed laws to regulate medical practice. In five of these States, viz., Alabama, Arkansas, Mississippi, North Carolina, Virginia (all Southern States, it will be observed), diplomas alone are not sufficient to give a man a legal standing. He must meet the requirements of the State Board. In two of these five States, all graduates are examined by County Boards, and all non-graduates by a State Board. In respect to the legal safeguards thrown about medical practice, North Carolina seems to be the banner State, and she seems to show her faith by her works; for at one of the recent meetings of her State Board, eleven out of fifty-three applicants were rejected, and seven more given leave to withdraw—a practical rejection of one-third of all the applicants.

These facts show that in some sections of the country, at least, the profession is alive to its own interests, and has succeeded in impressing the general public with a sense of its own relations to the important subject of medical education. The practical results in these foremost States have been decidedly encouraging. They have shown that requisite legislation can be brought by perfectly dignified and legitimate methods of agitation; and furthermore, that the enforcement of such legislation can easily be made an assured fact. The question has been agitated in our own State many times. The establishment of a State Board will do more than any other thing, perhaps, to raise the standard of medical education. We have often spoken of the material reasons which lead our medical schools to compete for the attendance of students. This competition is kept up year after year, and its outcome is a lowering of the standard of graduation requirements. The offer is virtually made to students, "Give us your money, and we will put you through." Another pernicious practice is the endorsing of diplomas from colleges in other States, in order to enable the holder of such diploma to obtain full standing under the present statutes. We are glad to note that the University of Pennsylvania has decided not to endorse any more diplomas, unless the applicant shall pass before its own medical faculty a full examination in the seven recognized departments of medical study, including pathology and morbid anatomy. In one of our recent Society meetings, a resolution was introduced looking to an investigation into the prevalent mode of endorsing diplomas. We trust that measures will soon be instituted which may lead to the abolition of the entire system.

The moment a State Board begins to demand a more thorough preparation on the part of men desiring to practise medicine, so soon will the medical colleges begin to demand some decent educational qualifications of its students. That institution which has the hardihood to take such a step and stick to it, will eventually be the gainer. Such a step would primarily result in a reduction of income; secondarily, the institution would be the gainer, because it would gather the best elements from the whole mass of students.

Practical precautions necessary for a State Board are forcibly expressed by Dr. Dabney. The Board should have no connection, collective or individual, with any teaching body. Its members should be nominated, at least, by physicians, who could better judge than laymen of the fitness of any particular man for appointment. It is in no trades-union spirit that these reasons are set forth. We have no right to say to a man or woman, you shall or you shall not study medicine. His or her claim to be allowed to practise must be substantiated before a competent Board of Examiners, free to act, knowing neither fear nor favor.

THE REACTION OF THE GENITAL DISCHARGES OF WOMEN.

SOMETIME ago M. Martineau announced that in blennorrhagia in the female the pus was acid, while in simple vaginitis its reaction was alkaline. The acidity of the blennorrhagic secretion was, therefore, a diagnostic point of much practical value. Since then Martineau has modified his statement, and only claims that the blennorrhagic pus is always acid, not that the secretions in simple vaginitis are invariably alkaline.

The statements made, however, have led Dr. P. Ménière, of Angers, to report the results of some investigations regarding "the chemical reactions of the normal and morbid humors of the female genital apparatus." Dr. Ménière asserts that the secretions of the vulvar sudoriparous glands, muciparous follicles, sebaceous follicles, and the vaginal wall are always normally acid, while the secretions of the glands of Bartholin and of the uterus are alkaline. In vulvitis and vaginitis, simple or specific, the reaction of the secretions is generally if not always acid. In endometritis the reaction of the pus is alkaline.

Dr. Ménière has extended his investigations into an inquiry as to the variations in the reactions of vaginal and uterine secretions in various morbid states. He announces to us as one result of his studies a point of distinction between the sexes which has not, we believe, been heretofore generally recognized, viz., that the "human organism is essentially alkaline," but that "woman is less alkaline than man." This alleged hypo-alkalinity, or extra acidity of the gentler sex has been perhaps noted already by philosophers and students of the domestic relations, but its existence has not been before placed upon a sound scientific and somatic basis.

Dr. Martineau has observed that in states of debility the alkalinity of woman, as measured by her vulvo-vaginal secretions, decreases, or, what amounts to the same thing, her acidity increases, yet the uterine reaction continues alkaline, though more feebly so. During pregnancy, and at about the time of the menses, the secretions from the genitals in women who are not in robust health may become too acid and cause a pruritus vulvæ. A case is reported in which a husband always got herpes præputialis during the latter part of his wife's pregnancy.

This increased acidity of the discharges in debilitated women causes in some instances sterility, and it is known that relief has been obtained for that condition by the use of alkaline injections. The larger amount of leucorrhœa in women who live in cities or under unhygienic conditions is attributed to this tendency on the part of the subacid sex to have too great acidity of their vaginal secretions.

MODERN METHODS OF PHYSICAL DIAGNOSIS.

THE art of physical examination of the chest for the purpose of obtaining objective evidence of disease has made considerable progress, even in late years, particularly in the refinements and niceties of such examinations. An admirable little work, recently written by Dr. Hudson,[1] gives one, in a concise way, an idea of the numerous methods and the elaborate technique which now make up the art of physical diagnosis of thoracic diseases. Years ago we recall studying a small manual in which we heard of very little except percussion and auscultation. Now we find eight methods of examination laid down, viz., inspection, mensuration, palpation, percussion, auscultation, auscultatory percussion, succussion, determining situation and size of surrounding organs, to which must be added, according to Dr. Arthur Ransome, the use of the stethometer and the study of vital capacities and of the respiratory and cardiac rhythm. In actual practice a very common and useful addition, also, to the methods of physical examination is the hypodermic syringe, by which the fact and the character of a pleuritic effusion can be absolutely established.

In the actual practice of physical diagnosis, however, it is still inspection, percussion, and auscultation which are the main sources of our information. Modern research has probably done more in the way of teaching the exact and careful use of those methods than in adding anything absolutely new to them. Still further, however, modern teachings give a vastly more correct interpretation of the significance of these signs which physical examination brings out.

It may be of interest to note the numerous technically recognized variations from health, as recorded by Dr. Hudson. On inspection one may observe abnormal expansion and bulging, retraction and depression, procidentia (of the shoulders and upper lung) and elevation, curvature, and distortion.

Palpation, or the laying on of hands, may reveal some half a dozen varieties of fremitus, viz., respiratory, vocal, tussal, bronchial, pulsatile, and friction. By percussion one gets variations in duration, intensity, and pitch, but especially in quality, of which the chest-wall produces six varieties: the hard, soft, tubular, amphoric and cracked-metal.

Naturally auscultation furnishes the richest evidence of pathological changes. We find recorded, for example, seventeen different changes from the normal conditions of the respiratory sounds. Besides these is the long list of rhonchi, râles, and pleuritic noises.

Students might well feel a little discouraged at the elaborateness with which the study of physical diagnosis has been carried out. Yet the mastering of the essentials is not a difficult task, provided our colleges can give the requisite clinical opportunities. And the discipline which results from a careful training in these details, all of which help to make our art more exact, is of immense value to the medical student. The besetting sin of many practitioners is their disinclination and incapacity to make thorough and searching examinations of their patients. It is the application of these and other methods of physical examination which will show eventually that science is a safer thing than quackery.

PRACTICAL MATERIA MEDICA.

A CORRESPONDENT sends us a vigorous and breezy communication upon the subject of practical medicine, and more especially upon the need of winnowing the chaff from the wheat of our materia medica. He refers in illustration to the immense amount of rubbish and uncertainty that there is in our present works, while in all other departments the student and physician is loaded

down with a mass of statements, discussions, and theories, which he thinks only confuse and hinder one in the practice of the medical art.

"Now the remedy," says our correspondent, "as I take it, will be the institution, in reality as well as in name, of a series of works known as 'Practical Materia Medica,' 'Practical Practice,' 'Practical Obstetrics,' etc.

"Permit me, in as few words as possible, to define what I mean by practical materia medica. Let us have a work embracing facts, and facts only; practical points, and practical points only; a full index and *no* preface. How in this realm of doubt can this be done? In this wise. Let us take opium for example. We certainly can give a clear history, and a careful description, including known incompatibles. Let us give such physiological effects on man (not grasshoppers, cats, and guinea-pigs), and *such* effects alone as are known and accepted by the medical world, carefully avoiding and excluding all points now in question. State that in some cases it produces wakefulness, but do not attempt to account for the fact. *Don't* say it is because the vaso-motor system of nerves fails to respond to the stimulus applied to the sympathetic system, thereby failing to produce that peculiar anæmia of the cerebrum necessary to the soporific effect. *Don't;* because some poor student will try to remember the unknown and imaginary reason and forget the fact. Let us take quinine. We all know that it cures ague, except in certain very exceptional cases, and why it don't cure those we *don't* know. Now if this were the only fact known to medical science, it would be enough to justify the beginning of a practical materia medica. We all know that in every case of fever resulting entirely or in part from septic poisoning, quinine has a wonderful antipyretic effect. We must needs, therefore, teach in our modern elaborate materia medicas, and in lecture-rooms, that quinine, without qualification, is a wonderful antipyretic.

"The result is our young graduate goes home, finds a robust farmer with an acute inflammation and temperature of 106° F., gives him promptly thirty grains of quinine, increases the fever, sets him crazy, and puts the whole house in an uproar, and finally goes back to his books, hoping to read, but really to meditate, on the uncertainty and often impracticability of medical science. We turn to our materia medica and find the officinal opium suppository one grain. No account of a suppository made containing less than one grain, and yet I remember, in my early practice, being called to see an old and feeble, but very influential gentleman, who died from opium-poisoning, produced by a one-grain suppository. Every good physician learns, not from materia medica but from his own experience and at the expense of his patients, the careful use of comparatively few remedies.

"There is no physician of more than five years' practice, let him be of high or low degree, who cannot recall many of his unsuccessful cases, which might have resulted favorably had his early teaching been eminently concise and practical. Let us admit no remedy, therefore, into our materia medica, except those endorsed, not by any single practitioner, but by the medical world. Do you think this a difficult task, and that one practical and compendious volume would contain no new remedies? How recent the discovery of cocaine, yet no doubt its history has reached every village and hamlet in the civilized world. Why are not our medical journals filled with the wonderful properties of Jamaica dogwood, manaca, and celerina? Nor will such practical work impede our rapid advancement, but rather greatly enhance it in this, that it will not be man's highest ambition to introduce a new and worthless remedy, or to model a new speculum, but to introduce a remedy or fashion a speculum that will find its way into our practical series, not only because of its intrinsic worth, but because it is recognized by the great thinking, throbbing medical world to be a thing of practicability and a joy forever.

"In THE MEDICAL RECORD of November 7th is a report of a meeting of the New York Academy of Medicine, held October 22d. Before the Section on Obstetrics a paper was read entitled, 'The Management of Unfavorable Cephalic Presentations at the Superior Strait,' wherein the writer maintains, with reference to diagnosis by digital examination, that 'one suture could not be distinguished from another with satisfaction; nor, by means ordinarily practised could the fontanelles be differentiated.' If this be true, why have we deluded ourselves into the belief that we *could* distinguish and differentiate? The writer further states, 'Something more definite must be searched for, and that was the ear, and to do that the hand must, to a greater or less extent, be introduced into the vagina.' In the discussion that followed, this proposition was universally admitted by gentlemen eminent in their profession. Where is the general practitioner, where is the new-born obstetrician, who has not sweat (figuratively) great drops of blood; who has not vilified his own stupidity in his endeavor to perform that which now, I believe for the first time, is *thoroughly* admitted to be *thoroughly* impracticable."

"In the name of *truth*, in the name of the *general practitioner*, but especially in the name of the *medical student*, let us have not only a practical materia medica but a practical practice, and a practical obstetrics."

Our correspondent is quite right in his advocacy of facts as the basis of our medical manuals. In materia medica, particularly, there is nothing more urgently needed than the elimination of a hundred or more useless or superfluous drugs. A society and a medical journal which would take for its object the showing what drugs are not needed would do for medicine an immense service.

THE MEETING OF THE STATE SOCIETY.

WE are glad to notice that the meeting of the Medical Society, held this week in Albany, has been a great success. Not for many years has the attendance been so large, nor during a similar occasion have a greater number of papers of merit been presented and discussed. The new plan of securing a provisional business committee has worked well. The distinguished President, Dr. Vander Veer, deserves the lion's share of praise for the manner in which he discharged the duties of his high office, and for the admirable and judicious presentation of the matters pertaining to the vital interests of the profession of the entire State. He voices the sentiments of the large majority of medical men of the Empire State when he refers, more in sorrow than in anger, to the recent disagreements regarding ethical questions bearing upon

the relations of the Society to the American Medical Association and the forthcoming International Congress. When these differences are calmly discussed they sink into comparative insignificance. Already the properly conservative elements of both parties, not only in this State, but elsewhere, have the whole matter entirely in their hands, and will, we doubt not, be soon ready to meet on a common platform of harmony. In reality we are not far from it already. The sooner the extremes of both sides cease to pose as martyrs, and sink purely personal issues, the sooner will the proper reconciliations be made. But this is only by the way, and the Medical Society of the State of New York, more powerful and more successful than ever, is disposed to be reasonable, conservative, and just. The question of State examinations in medicine comes up yearly, but none too often until it is settled against the avowed and purely private interests which now so actively oppose it. The time must come when we must have independent State examinations in medicine, whether the colleges like it or not. If we fail one year, we are willing to try it the next. The scientific element of the meeting was well represented by leading men from the principal cities, our own little town offering its mite. The papers were, as a rule, short, practical, and therefore instructive. It is sometimes astonishing to see how much limited time and space will do toward shortening sentences, condensing sentiment, and quickening wit.

News of the Week.

The Work of the Small-pox in Montreal.—We learn from the Secretary of the National Board of Health that the total number of deaths from small-pox in the city of Montreal, from the beginning of the epidemic in April to December 31st, was 3,164, as follows: In April, 6; May, 10; June, 14; July, 46; August, 239; September, 659; October, 1,393; November, 633; December, 165. There were also 363 deaths from measles, typhoid fever, and diphtheria during the year, and the total mortality from all causes during 1885 was 7,885, as against 4,358 during 1884.

Cholera in Japan, Spain, and France.—Dr. W. P. Dunwoody, Secretary of the National Board of Health, writes that the United States Consul at Hioga, Japan, reports that during the month of October last 1,208 cases and 628 deaths from cholera were reported in Osaka vicinity, and in Hioga and Kobe there were 354 cases and 227 deaths from cholera during the same period. During the month of November there were 58 cases and 47 deaths from cholera. In the province of Huelva, the extreme southwestern province of Spain, there were, from November 6th to 26th, 42 deaths from cholera. In France, the cholera was still prevalent in the Department of Finistère on December 7th, the date of our last report. During the twelve days from November 26th to December 7th, inclusive, there were 160 cases and 62 deaths.

Æsculapia Victrix.—Under the title "Æsculapia Victrix" Mr. Robert Wilson contributes to the current number of the *Fortnightly Review* an interesting account of the rise, struggles, and present position of the London School of Medicine for Women. This brief sketch of the origin and history of the movement for educating women to undertake the duties of professional life is presumably, says the *Medical Press and Circular*, designed to reawaken the sympathy of the public on behalf of an object that is undeniably a good one, and which just now derives additional importance in connection with the movement in which Lady Dufferin is deeply interested, for supplying female physicians to act as medical attendants to the native women of India. More money is needed to help on the school.

"Wonderful Surgical Operations."—New York, Philadelphia, and other medical centres are not alone in being treated by the daily press with accounts of "wonderful operations." Sir William MacCormac recently performed tracheotomy at St. Thomas's Hospital, and the operation and operator received the admiring comments of the *Daily Mercury* and other papers.

Trouble in the Philadelphia County Medical Society.—As misery is reported to be fond of company, New Yorkers may perhaps sympathize with their Philadelphia brethren in their present trouble. The Philadelphia *Medical Times* says: "At the stated meeting of the Philadelphia County Medical Society held on January 6th, for the purpose of electing officers, the regular nominations for delegates to the State organization and the American Medical Association were set aside, and a new ticket introduced and elected by a proceeding without a precedent in the history of the Society. Now that the meeting is over, and we review its proceedings, we feel that no one who was present can escape a sense of mortification at the disorder which prevailed during the discussion, if not of regret for the results of the ballot. It is true that, by the concerted action of one hundred and fifty members, the Society (whose entire membership is nearly five hundred) finds itself with a bad precedent established, and with a lively factional quarrel in prospect."

An Inquiry into the Abuses of Medical Charity in Liverpool, recently made, showed that 298,000 persons received gratuitous medical relief annually in that city. There were forty-eight medical relief societies, with an annual income of over two hundred thousand dollars.

Patients' Names and Patients' Secrets.—A German practitioner has been sentenced to a fine of $375 for "unauthorized publication of secrets." He seems to have been exorbitant in his fees; but the offence with which he was charged was that of displaying, in a public refreshment-room, a bill of fees to a certain gentleman, which set forth that the attendance was on his wife for a "sexual complaint." The laws in most continental countries distinctly recognize the obligation of medical men to keep the secrets of patients whom they attend professionally.

As One Result of the Hydrophobia Scare in London, seventeen thousand dogs have recently been suffocated.

A Medical Diplomat, M. Paul Bert, has been appointed Minister Resident in Annam, Tonquin, and Gambodia.

THE PAUPER LUNATICS of England cost the government nearly two and a half millions last year. The lunatic asylums of the United States cost about fifteen million dollars annually.

A PROJECT TO ESTABLISH A NATIONAL BUREAU OF HEALTH AT WASHINGTON.—Representative Davis, of the Fall River district of Massachusetts, introduced during the past week a bill "to prevent the introduction of contagious and infectious diseases into the United States, and to establish a bureau of public health." It provides for the appointment by the President, with the approval of the Senate, of a Commissioner of Health, to be chosen from civil life, and to receive a salary of $4,500 a year. He is to be the head of the bureau, which is to be attached to the Department of the Interior. The Department of State is required to obtain from consular officers in foreign ports and places all available information in regard to the sanitary condition of such ports and places, and transmit the same to the bureau. The Commissioner, under the direction of the Secretary of the Interior, is to frame rules which, when approved by the President and issued by the Department of State, shall serve for the instruction of consular officers of the United States, and of the medical officers serving at any foreign port. In compliance with these rules every master of a vessel destined for a port of the United States must be furnished with a certificate containing a detailed statement of the inspection of the vessel, cargo, crew, and passengers, and of the sanitary measures carried out at the expense of the vessel; or, if such measures are not carried out, instant warning is to be transmitted to the bureau. The bureau is charged with the investigation, both in this country and in others, if necessary, of the nature, origin, and prevention of infectious and epidemic diseases, as well as of the causes and conditions of particular outbreaks of disease in the United States, and with the publication and distribution of documents relating to the prevention of disease. The President is authorized, when requested by the bureau, to detail officers from the several departments of the Government for temporary duty, to act under the direction of the bureau without extra compensation; and when a detail of suitable officers cannot be made, the Commissioner may employ experts for such time and in such manner as the funds at the disposal of the bureau may warrant. The bill appropriates $75,000, to be disbursed under the direction of the Secretary of the Interior, on the requisition of the Commissioner of Health; repeals the law of 1879 establishing the National Board of Health, and is to go into effect sixty days after its passage, within which time the Commissioner is to be appointed.

THE HOUSE OF JOHN HUNTER.—Mr. John J. Merriman writes to the *British Medical Journal:* "The house which John Hunter built in 1764, on his own freehold at Earl's Court, Kensington, together with the grounds, dens, etc., so little changed since his day, will soon be obliterated; and those members of the profession who care once again to visit the home of 'the greatest man, in the combined character of physiologist and surgeon, that the whole annals of medicine can furnish' (Sir William Lawrence), should go to Earl's Court House without delay. When Frank Buckland visited this historical spot, on June 23, 1871, he wrote: 'I almost imagined I was in the presence of the great man himself, so little is the place changed.' A full account will be found in *Land and Water*, July 6, 1871, and also in Buckland's 'Logbook of a Fisherman and Zoologist,' 1875. The memory of John Hunter will always be kept up by his immortal discoveries in surgery, physiology, and natural history, by his Museum at the Royal College of Surgeons, and by the window in the parish church of Kensington, but many will lament the demolition of that 'Home' in which he worked so vigorously for nearly thirty years."

THE JOHNS HOPKINS UNIVERSITY AND ITS MANAGEMENT.—A correspondent in Baltimore writes us: "For some time past there has been considerable dissatisfaction with the manner in which the 'Johns Hopkins' bequest is handled. An effort was made by the minority of the trustees to have the University opened some months ago, but they were outvoted. The same gentlemen, knowing Mr. Hopkins' wishes in the matter, desired the University to be located at Clifton, the beautiful country residence that Mr. Hopkins donated for this particular purpose. Again were they voted down. A bill has been introduced into the State Legislature, asking that a committee be appointed to ascertain whether the wishes of Mr. Hopkins have been carried out or not."

A HEALTH DEPARTMENT FOR JAPAN.—A Health Department has been established in Japan under Dr. Mansanori Agata, Professor of Hygiene in Tokio, who studied for several years in Munich, Leipsic, and Berlin, and in particular worked for a lengthened period in the laboratories of Pettenkofer and Koch. Since his return to Japan he has carried out the German methods of bacteriological research, and has by this means investigated the disease beri-beri, which is indigenous to Japan.

VEXATIOUS DELAYS IN LUNACY CASES.—Dr. E. C. Spitzka, of this city, writes: "In regard to the letter of Dr. Hardy, published in your issue of January 30, 1886, and in which he states that he has not been subjected to 'vexatious delays,' that he has always found the judges 'agreeable and accommodating,' and in which he takes exception generally to some statements made in an editorial of THE MEDICAL RECORD of January 9th, permit me to state the following: (1) Dr. Hardy's statement is correct as far as most of the judges of the New York Supreme Court (particularly Judge Donohue, who actually goes out of his way to accommodate physicians) are concerned. (2) Dr. Hardy is known to the majority of the intelligent members of the bench (who do not necessarily constitute a majority) as the examiner in lunacy matters for the City Prison and Reception Pavilion of Bellevue Hospital, and naturally has privileges accorded him which the general practitioner seeks in vain. His experience with judges is therefore exceptional. (3) Dr. Hardy, if he desire to commit a patient before a judge of the New York Superior Court, will be compelled to fee the clerks of this court. The undersigned and one other physician are willing to make an affidavit to the effect that such a fee, as well as other compliances with an absurd and antiquated red-tape system, are required of him in the presence of the chief clerk of said court. (4) Individually, I am willing to make an affidavit to the effect that, in so far as the

Superior Court, through its clerks and other so-called officials, extorts fees from physicians as a condition of approving certificates of insanity, it does not do so in compliance with any legal enactment, or in obedience to any principle of common law or of common sense. Probably the judges know nothing of this practice, which is merely a collateral source of income for a pair of hungry clerks. The fact that the Supreme Court and the Court of Common Pleas approve such certificates without this absurd and mercenary routine demonstrates the truth of the above proposition. (5) The writer, like Dr. Hardy, has an intimate knowledge of law courts and some acquaintance with judges, and has had repeated occasion to express his gratitude to members of the bench for their complaisance and courtesy in cases where the urgent commitment of an acute or dangerous lunatic was required. But where does the general practitioner, although he be a qualified examiner in lunacy, come in? Who is compelled by law to do the legal part of that duty of which the physician is compelled to take the moral and (if sued) the financial responsibility?"

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eightieth Annual Meeting, held in Albany, N. Y., February 2, 3, and 4, 1886.

FIRST DAY—TUESDAY, FEBRUARY 2D—MORNING SESSION.

THE Society convened in the Common Council Chamber, City Hall, and was called to order at 10 o'clock by the President, DR. ALBERT VANDER VEER, of Albany. Prayer was offered by REV. WALTER D. NICHOLAS.

The PRESIDENT then delivered his inaugural address, at the close of which he appointed the following

COMMITTEES.

Business Committee—Drs. W. W. Potter, of Buffalo, Daniel Lewis, of New York, and A. M. Phelps, of Chateaugay.

Committee on Credentials—Drs. S. W. Freeman, of Albany, W. B. Chase, of Brooklyn, and McFee, of Franklin.

INAUGURAL ADDRESS.

After thanking the Society for the honor it had conferred upon him, and making reference to the new law permitting the Society to regulate its own membership, the President recommended that every alternate year the meeting of the Society be held in some other part of the State than Albany, the place to be determined by the Nominating Committee; called attention to Dr. Jacobi's circular concerning collective investigation of disease; and that the power lodged in the Regents to confer the honorary degree of medicine should be a matter for consideration at this meeting.

He then referred to the humiliating action of the American Medical Association at its meeting held in New Orleans, with reference to the International Medical Congress, the result being that the meeting of the Congress has been rendered doubtful, or, if it meets, its success has not been insured. Reference was also made to the interpretations given by the American Medical Association as a step in the right direction, differing but little from our own view of the question.

He also acknowledged the receipt of a circular from the American Medical Association, concerning the securing of a law which would establish a State Board of Medical Examiners, and the President expressed the hope that we might soon see State control doing that good which has already been accomplished in other States.

He also urged that steps be taken to add to the medical library, and recommended that his successor continue a temporary Business Committee which had so greatly facilitated the work of the present meeting.

Special reference was made to the deaths which had occurred during the last year, and special mention was made of Norman L. Snow, of Albany, with Little and Elsberg, of New York, W. W. Porter, of Syracuse, W. B. Carpenter, and Dr. Van Dusen.

In conclusion, the President announced the serious illness of our honored Vice-President, Alfred C. Post, M.D., LL.D., of New York.

At the conclusion of the address, DR. S. OAKLEY VANDER POEL, of New York, offered a resolution expressing the sympathy of the Society with Dr. Post in his illness, and expressing the earnest hope that he may speedily recover, which was unanimously adopted.

DR. W. W. POTTER, Chairman from the Business Committee, recommended the appointment of a committee to invite the members of the Legislature, the Governor and Lieutenant-Governor, and other *ex-officio* honorary members, to attend the meeting of the Society.

THE PRESIDENT appointed Drs. W. C. Wey, of Elmira, H. G. Piffard, of New York, and W. E. Ford, of Utica.

The Business Committee also recommended the appointment of a committee on the President's inaugural address.

The Committee consisted of Drs. F. R. Sturgis, of New York, W. S. Ely, of Rochester, and H. S. Hopkins, of Buffalo.

INVITED GUESTS.

DR. S. B. WARD, of Albany, Chairman of the Committee of Arrangements, announced the following: Drs. J. L. Corning, Ephraim Cutter, Robert T. Morris, William Stevens, of New York; N. A. Powell, of Ottawa, Canada; Frederick Petersen, of Poughkeepsie; Samuel Morris, of Albany, and G. H. Pryor, of Buffalo.

COMMUNICATIONS FROM COUNTY MEDICAL SOCIETIES.

BIOGRAPHICAL SKETCHES.

DR. WESLEY M. CARPENTER, of the County of New York, presented biographical sketches of James L. Little, M.D., by D. B. St. John Roosa, M.D., LL.D.; and Louis Elsberg, M.D., by Morris H. Henry, M.D., LL.D., which were referred to the Business Committee and subsequently recommended for publication.

Dr. Carpenter also presented amendments to by-laws which had been adopted by the Medical Society of the County of New York, which were referred to the Committee on By-Laws.

REPORT OF THE COMMITTEE ON LEGISLATION.

DR. F. R. S. DRAKE read the report, which gave a brief review of the work done by the Committee during the year. It also appeared that the bill providing for a State Board of Medical Examiners had been again introduced into the Legislature.

The Act to enable the Medical Society of the State of New York to regulate its own membership had become a law. The report of the Committee was accepted and adopted.

An excess of $98.00 expended by the Committee was ordered paid.

The Business Committee recommended that the time for each reader of a paper be limited to *twenty minutes, maximum.* Adopted.

DR. C. L. STILES, of Owego, then read a paper containing the history of a case of

ABSCESS OF THE KIDNEY

occurring in a man fifty-seven years of age, the result of traumatism, and in which there was very notable increase

in the size of the tumor in twelve hours, without rigor or pain, attended by a small amount of pain and general disturbance during the illness, and accompanied by a sudden discharge into the bladder.

Dr. J. Leonard Corning, of New York, invited guest, read a paper entitled

THE CURATIVE POTENCY OF PROLONGED SLEEP,

and in which he also referred to the potent influence of scientific feeding. He spoke of three conditions, muscle rest, spinal rest, and cerebral rest, and while considering these conditions mentioned Weir Mitchell's method of treatment for these classes of cases as the most efficient, except for cases of cerebral exhaustion and irritability, where confinement in bed is positively harmful.

The paper was referred to the Committee on Publication.

Dr. B. F. Sherman, of Ogdensburg, then read a paper in which he reported

A CASE OF EMPYEMA

treated successfully by the use of the valvular drainage-tube and improved aspirator devised by Dr. A. M. Phelps, of Chateaugay, and presented to the Society *six* years ago. The patient was a male nineteen years of age, and complete expansion of the lung took place.

Dr. W. S. Ely, of Rochester, then read a paper on a cognate subject, that of

PULMONARY CAPACITY,

in which he spoke of natural and acquired defective chest expansion, and advanced the view that lung expansion can be relatively increased by a series of exercises which may be called pulmonary gymnastics; this can be accomplished by bringing into special exercise the auxiliary respiratory muscles. He believed that the subject was of sufficient importance to secure the attention of medical men, to whom such cases should be referred exclusively for the instructions proper to be observed in each case. The mode of management is not applicable to acute cases.

Discussion on both papers was opened by Dr. A. M. Phelps, who described his valvular tube, and gave the credit to Dr. Lee, of London, who published the same views a short time before he read his paper before this Society. The aim is to obliterate the pus cavity, which is accomplished by emptying it of its contents and then approximating its inner surfaces. In the case of empyema, the yielding surface is the lung, which is capable of expansion.

Dr. A. L. Loomis, of New York, said that the length of time the lung may be crowded up under the clavicle, and yet be restored to its normal condition, depended upon the amount of change in the pulmonary pleura; if there is no change the lung may remain compressed, and perfect expansion occurs when the fluid is removed.

With regard to the treatment which will result in the perfect expansion of the lung in cases of acute suppurative pleurisy, such as Dr. Sherman's was, if compression was removed within one or two months, certainly if within one or two weeks, we might expect complete expansion of the lung. In such acute cases the fluid should be removed as soon as it is formed, and aspiration is rather worse than no treatment, according to his experience. The only proper course is to make a free opening at the most dependent part of the cavity—a single one is usually sufficient, if made early—and the introduction of a drainage-tube. If the pus is not gangrenous, has no odor, he believed that washing out the cavity is entirely unnecessary.

With regard to pulmonary gymnastics presented by Dr. Ely, if applied when the person is below par, they enfeeble rather than invigorate. Pulmonary gymnastics for pleuritic adhesions, and in pulmonary diseases, is another question. With regard to prolonged muscular effort, such as rowing, etc., in young men developing, he believed, was laying the foundation of cardiac disease and of pulmonary phthisis in very many cases.

Dr. Jacobi, of New York, favored washing out the pleural cavity when the fluid contained flocculi, and said that if the operation in empyema was performed antiseptically, and the chest dressed with the same precautions, the dressings need not be removed oftener than once in three, four, or five days, perhaps longer, and in this way favored the reduction of the quantity of fluid in the pleural cavity.

With reference to Dr. Ely's paper, there was one class of cases in which such management was beneficial, namely, those in which ossification of the upper cartilages of the ribs occurred so as to narrow that portion of the chest. By such treatment the lung might be expanded considerably upward and downward.

The paper was further discussed by Dr. Fraser, of Camden, Oneida County, and Dr. F. A. Castle, of New York.

Dr. Herman Bendell, of Albany, read a paper on

THE TREATMENT OF AURAL POLYPI BY THE INJECTION OF CARBOLIC ACID,

which he regarded as a more satisfactory method than either operative procedures or the use of caustics and astringents.

Dr. Thomas R. Pooley, of New York, objected to carbolic acid because of the possible occurrence of pyæmia or septicæmia, and the difficulty of limiting the sloughing. He employs avulsion, and said that the hemorrhage attending this operation in his experience had been insignificant.

Dr. Sherman, of Ogdensburg, had used tannic acid in these cases with good results.

Dr. W. F. Mittendorf, of New York, said that the plan of injecting with carbolic acid originated with him about the year 1881, but he limited its use to cases in which the growth presented at the external meatus. The operation, however, had proved so painful that he had abandoned it entirely, and now resorts to the use of the snare.

Dr. O. D. Pomeroy, of New York, said that injection of aural polypi was destructive, painful, and also unnecessary, as there were other and better means for their removal. He uses the forceps and cauterizes the base with nitrate of silver.

Dr. D. B. St. John Roosa, of New York, read a paper entitled

RESULTS OF THE OPERATION FOR CONVERGENT SQUINT.

in which he stated his belief that the operation is permanently successful, if properly understood. There is, however, a division of sentiment on this question. The most favorable time for operation is between five and seven years of age, and vision can be rendered clearer by the use of glasses in a large proportion of cases. There is never any substantial improvement of the vision of the squinting eye by the operation for squint; the improvement in vision is not due to the operation, except in so far as it places the patient in a condition to wear glasses. The operation may successfully remove the deformity in seventy or eighty per cent. of the cases of convergent squint, and this percentage may be raised to ninety-five per cent.

Dr. Harvey Jewett, of Canandaigua, read a paper containing the history of

A CASE OF VESICAL CALCULUS

occurring in a woman sixty-eight years of age, and in which one stone weighing one hundred and eighty-six grains was expelled spontaneously, and another weighing three hundred and ninety-five grains was removed by forceps.

The Society then adjourned to meet at 2.30 P.M.

AFTERNOON SESSION.

The Society was called to order at 2.30 P.M. by the President.

COMMITTEE ON NOMINATION.

The following were reported as the persons elected for the Committee on Nomination by the meetings of the several Senatorial districts:

First District.—Laurence Johnson.
Second District.—H. R. Winter.
Third District.—William H. Bailey.
Fourth District.—Frank G. Buckbee.
Fifth District.—George Seymour.
Sixth District.—William C. Wey.
Seventh District.—F. M. Hamlin.
Eighth District.—John O. Roe.
Member appointed by the President.—S. Oakley Vander Poel, of New York.

DR. GEORGE R. FOWLER, of Brooklyn, read a paper entitled

COMPARISON OF THE MODERN METHODS OF TREATING UNUNITED FRACTURES,

included under two heads, non-operative and operative methods.

Of the non-operative there were fixed dressings, friction of the fractured ends, subcutaneous puncture, aided perhaps by injection of irritating fluids. All these are open to the common objection that they are not applicable in the vicinity of joints.

The percussion method of Thomas, of Liverpool, he had resorted to with good results in several cases. The method consists in placing a folded towel over the parts, and then hammer them until an active degree of inflammation is established.

Mention was then made of the use of ivory pegs, with results far from satisfactory, and the use of steel screws, a modification of Dieffenbach's operation.

INVITED GUESTS.

DR. W. S. ELY, of Rochester, reported the following: C. C. Rice, of New York; W. G. Tucker, of Albany; E. B. Bronson, of New York; James Craig, of Albany; W. S. Daly, of Ogdensburg; D. McFalls, of Gouverneur; C. M. Leffler, of Gloversville; S. E. S. H. Nott, of Erie County; O. D. Ball, of Albany; A. S. Newcomb and O. D. Pomeroy, of New York.

Dr. Ely also introduced as

DELEGATES FROM ABROAD,

T. J. Allen, of Montreal; William Gardner and James Stewart, of McGill University; and T. J. Alloway, of Montreal.

A paper by Dr. N. A. Powell, of Ottawa, Canada, on "Vesical Calculi in Children," was read by title and referred to the Committee on Publication.

THE COMMITTEE ON PRIZE ESSAYS

reported that only one essay had been submitted, and that in their opinion it was unworthy of the prize.

DR. C. H. PORTER, of Albany, offered the following

AMENDMENT TO THE BY-LAWS AFFECTING PERMANENT MEMBERSHIP.

To Article 1, Section 5, shall be added: "All persons now eligible, and who have not been nominated as permanent members, upon notifying the Secretary of this Society of their desire to become such, will become permanent members on complying with the By-Laws." Adopted.

DR. A. HADDEN, of New York, then read a paper on

RHEUMATIC AFFECTIONS OF THE JOINTS,

in which he spoke especially of the morbid condition in different classes of cases, their etiology and treatment.

DR. THOMAS R. POOLEY, of New York, read a paper which contained the history of a case of

SARCOMA OF THE ORBIT AND ANTRUM.

The patient was operated upon, the neoplasm removed, and he was discharged from his hospital at the end of about one week with the operative wounds nearly healed.

The paper was discussed by the President and Dr. E. Hutchinson, of Utica.

INFANT FEEDING.

DR. E. F. BRUSH, of Mt. Vernon, read a paper on the above subject, in which he pointed out some simple methods of feeding an infant when it has been deprived of the breast. He urged the claims of simple foods in preference to the so-called "patent foods," the composition of which was often unknown; he examined the composition of the once famous "Liebig's Food for Infants," and another popular food, and indicated the dangerous amount of alkali contained in them, citing Dr. Jacobi's warning that "we are not very careful in doses of alkalies in general," and Dr. Stillé's remark that alkaline treatment "lessens the amount of fibrin in the blood." He showed by the figures of an advocate of peptonized food, that the results of such feeding were not satisfactory.

Proceeding then to the immediate subject of his paper, he stated that one of the greatest elements of failure in the artificial feeding of infants was the desire to give one sort of food alone, under all circumstances, and hence the blind prescription of patent foods. He advised, on the contrary, the preparation of foods from simple articles within reach to meet the requirements of each case as they arise. When with food thus prepared there is a failure, the physician has at least the knowledge as to what the failure arises from.

Commencing then with the child at birth, Dr. Brush gave his formula for the best substitute for colostrum, and his further treatment if the cathartic effect was either excessive or defective. He then discussed what was the best staple food. He answered unhesitatingly, "cow's milk," which, however, was subject to many conditions that render it unfit, unless due care is exercised. In 1879, Dr. Brush had pointed out the difference between the milk of the ruminant and non-ruminant animals, as regards particularly the quantity and quality of the casein contained in them, and the difficulty experienced by the human young in digesting a milk intended for bovine young. When an infant vomits a hard curd, the indications are that the milk must either be prevented from coagulating in the stomach, or coagulated and broken up before entering the stomach. He showed that it was inadvisable to use an alkali to overcome the tendency to souring in the stomach, and therefore recommended the latter treatment of coagulating and breaking up the milk before feeding it. In other cases he recommended the addition of lime-water as the safest agent, as it did not, like other alkalies, keep the stomach in an alkaline condition, nor cause an acid condition of the intestines. In cases of diarrhœa in children fed on milk, the indications were to stop the milk immediately. The milk was usually the cause of the trouble, and the milk was rendered unfit by the physical condition of the cow, such as œstrum pregnancy, poisonous herbs, cruel treatment, and the like, to all of which states many cases of diarrhœa in infants could be traced.

In these cases of diarrhœa he recommended oatmeal water, which his analysis convinces him was somewhat similar to milk in composition. He insisted on the necessity of the medical attendant himself preparing and teaching the preparation of these simple foods. In all cases, however, the child should be put back on its ordinary milk diet as soon as possible.

As regards the kind of cow best adapted to supply milk, Dr. Brush prefers the common grade cow to the Jersey or fancy breeds; the latter are of a tuberculous tendency; the fat in the milk is not sufficiently emulsified, and they are of higher nervous temperament, while the

common cow ordinarily is gentle and a good feeder. She should always be stall-fed, as in hay even the poisonous weeds lose the evil properties by the desiccation of the volatile poisonous principle. When milk has been bought, that of one cow should always be avoided. In cases of constipation raw-malt water, carefully prepared as a diluent of the milk, is efficacious. In acute dysentery raw-beef solution is to be recommended. In all cases of dysentery the food should be warm.

The paper was discussed by Dr. A. Jacobi, of New York, who spoke especially of the following formula, devised by Dr. Rudisch, of New York, for rendering the curd of cow's milk flaky and soft:

Dilute muriatic acid (officinal), twenty-five or thirty drops; water, one pint; and cow's milk, one quart. Mix and boil.

Dr. A. Jacobi, of New York, then read a paper on

PAPAYOTINE

in the treatment of diphtheria. He had used it in the following mixture: *one* part of the remedy, *four* parts of water, and *four* parts of glycerine; applied locally, and with a good degree of success in softening and dissolving the membrane. Illustrative cases were reported. It can also be used one part to two of water and two of glycerine, and applied quite constantly.

Dr. Alfred L. Loomis, of New York, then read a paper on

GENERAL ARTERO-CAPILLARY FIBROSIS,

in which he discussed its relation to cardiac and renal disease. He regards it as a general condition which involves the vascular system, and manifests itself in a variety of morbid changes in different parts of the body. The effect of the fibroid degeneration is to diminish the calibre of the arterioles. It is to be recognized by the character of the pulse, it giving evidence of increased arterial tension. The relation which left cardiac hypertrophy has to the small kidney was discussed at length, and the relation which both morbid conditions sustain to a general fibroid condition of the arteries and arterioles was demonstrated.

Dr. H. R. Hopkins, of Buffalo, read a paper on

ULCERATIVE ENDOCARDITIS,

in which he discussed the question of its primary occurrence, its symptomatology, and its etiology. Whether primary or not is questionable. In the vast majority of cases it is secondary, especially to scarlet fever, pneumonia, and pyæmia. He thought one should be guarded with reference to expressing an opinion concerning the etiological relation existing between the disease and micro-organisms, although the relation of cause and effect was maintained by many observers.

The paper was discussed by Drs. Jacobi and Loomis, of New York; Ely, of Rochester; and Hopkins, of Buffalo.

Dr. Willis E. Ford, of Utica, read a paper on

THE EARLY MANAGEMENT OF CASES OF MENTAL DEPRESSION,

in which he presented two classes of cases: first, intellectual; and, second, emotional.

The paper was discussed by Dr. Roosa.

Dr. J. M. Bigelow, of Albany, read a paper entitled

HINTS ON THE TREATMENT OF DIPHTHERIA,

in which he referred to the successful use of pilocarpine, the topical use of carbolic acid, followed by the use of a solution of lactic acid, together with the internal use of the muriated tincture of iron.

INVITED GUESTS.

The following were announced: Drs. Maurice J. Levi, Daniel V. O'Leary, D. H. Cook, David Fleischman, and F. J. Classen, of Albany; James Ferguson, D. H. Goodwillie, and W. C. Phillips, of New York; James A. Sinclair, of Canajoharie; J. L. Heffron, of Syracuse; Hiram Wiggin, of Elbridge; and Dr. Layman, of Schoharie.

The society then adjourned to meet at 8 P.M.

EVENING SESSION.

The Society was called to order by the President.

In the absence of Lawson Tait, F.R.C.S., of Birmingham, Eng., Dr. S. B. Ward, of Albany, read his paper (see p. 141) on

METHODS OF DIAGNOSIS

Dr. W. Gill Wylie, of New York, then read a paper on

DISEASES OF THE FALLOPIAN TUBES,

reported cases, and exhibited characteristic specimens.

"Since May, 1883, I have operated on thirty-seven women for the removal of diseased uterine appendages, not including ovariotomies and other operations for large tumors of the ovaries. Twenty-five of these have been reported (fourteen January 15, 1885, and eleven June 19, 1885) in The Medical Record of February 7, 1885, and August 29, 1885.

"Of the thirty-seven, thirty-three recovered and four died. Two of the latter were complicated by pelvic abscesses at the ends of the tubes and around the ovaries; a third was complicated by hæmatocele attached to the left ovary; and the fourth, on account of extensive adhesions and degenerated state of the ovaries, required considerable exposure of the peritoneal cavity in operating. Thirty-four of the thirty-seven cases had marked peritoneal adhesions. More than one-third were well-marked cases of pyo-salpinx, and nine were either complicated by abscesses or the tissues about the tubes and ovaries were infiltrated with pus.

"Twenty-three were hospital cases, and were chiefly selected from three large dispensary clinics, where every year hundreds of women suffering from local peritonitis, the result of diseased tubes or septic poison reaching the peritoneal cavity through the Fallopian tubes, present themselves for treatment. If one would follow the text-books on gynecology, most of these thirty-seven cases would have been classed as chronic cellulitis; four or five would have been called cases of pelvic abscess, and quite a number would have been called ovaritis.

"With the exception of three or four cases operated upon for cystic degeneration, which was supposed to be the cause of hystero-epilepsy, almost all were at times bedridden by repeated attacks of local peritonitis. It is yet too soon to speak positively about the results of the operations in all classes of cases, but I can say without hesitation that, in those cases where the subjective symptoms were chiefly actual local pain and physical inability to go about without causing persistent pain—and almost all of the cases of pyo-salpinx would come under this head—the results were good and satisfactory both to the patient and doctor. In many cases the relief from pain was gratefully acknowledged at once.

"In those cases where the subjective symptoms were chiefly reflex, and of a nervous order, the immediate results were by no means always satisfactory, although many completely recovered after seemingly being unimproved for several months. I have repeatedly refused to operate on this class of cases, unless I could plainly make out by bimanual examination that the ovaries were enlarged by cystic degeneration. I have yet to see a well-marked case of hystero-epilepsy or decided hysteria operated on where the ovaries were not found in a state of cystic degeneration, or very much atrophied. And these are nearly always associated with an imperfectly developed or atrophied uterus.

"The class of cases which will not only test the educated sense of touch and practical ability to diagnose and skill to do a successful operation, but will also give many opportunities to actually save life, are to be found among those cases complicated by small pelvic abscesses. The

ability to diagnosticate will be shown by detecting them before they have either penetrated into the connective tissues below the peritoneum and formed large pelvic abscesses, or, what is of still greater importance, before they have broken through the layer of lymph thrown out by the peritoneum to shut the diseased organ and tissue from the peritoneal cavity, and caused general peritonitis and death. The skill in operating will be shown by either removing intact the diseased organ and sac of the abscess, or by removing most of the sac and washing and draining the peritoneal cavity to avoid septic poisoning and death."

The surgical pathology was given as recorded in THE MEDICAL RECORD, January 24, 1885.

These papers were discussed by Dr. Paul F. Mundé, of New York; the President, Dr. Hailes, of Albany; and Dr. W. B. Chase, of Brooklyn.

The discussion was closed by Dr. Wylie.

DR. DANIEL LEWIS, of New York, presented the subject of

THE PHYSICIAN'S MUTUAL AID ASSOCIATION,

which can now receive members from all the counties of the State.

DR. P. A. FURBECK, of Gloversville, then read a paper on

THE ESTABLISHMENT OF A STATE BOARD OF MEDICAL EXAMINERS.

The writer favored the creation of such a board, and the bill substantially which was approved by the Society at its last annual meeting; one of the chief exceptions being with reference to where the examinations should be held, believing it best that they should be conducted at the colleges.

The paper was referred to the Committee on Legislation for consideration.

A paper on cholera, by J. A. S. GRANT (Bey), of Egypt, was read by title and referred to the Committee on Publication.

The Society then adjourned to meet on Wednesday at 9 A.M.

SECOND DAY—WEDNESDAY, FEBRUARY 3d—MORNING SESSION.

The Society was called to order at nine o'clock by the President, and prayer was offered by REV. R. W. KENYON.

REPORT OF THE COMMITTEE ON BY-LAWS.

DR. W. C. WEY, of Elmira, Chairman of the Committee, reported that, concerning the communication from the Cayuga County Medical Society, the act passed by the Legislature relating to permanent membership, already reported to the Society, will relieve that Society from further vexation and grief; that they withhold their sanction from the amendments to by-laws, adopted by the Counties of New York and Yates, making provision for the dropping of members for non-payment of dues.

The report of the committee was, after limited discussion, adopted.

DR. R. H. DERBY, of New York, presented the subject of

COMMUNICABLE EYE DISEASES,

and the bill recommended by the New York Academy of Medicine. The communication was received and the bill endorsed.

DR. C. H. PORTER, of Albany, Treasurer, presented

THE TREASURER'S REPORT,

which was referred to an Auditing Committee consisting of Drs. J. E. Potter, of Delphi, Onondaga County; W. H. Craig, of Albany; and M. H. Turner, of Essex County. Dr. Porter also reported on the Merrit H. Cash Fund, which was excepted.

DR. H. G. PIFFARD, of New York, offered a resolution appropriating $300 for the use of the Committee on Legislation. It gave rise to discussion, and was lost.

DR. E. L. PARTRIDGE, of New York, from the Committee of Arrangements, reported the following

INVITED GUESTS:

George B. Dunham, of Plattsburg; S. J. Banker, of Fort Edward; C. L. Fletcher, of Dutchess County; J. H. Smith, of Dannemora; F. H. Bosworth, of New York; A. Ten Eyck, of Blooming Grove; L. Howe, of Buffalo; J. D. Featherstonhaugh, of Cohoes; F. H. Potter, of Buffalo; E. L. Keyes, W. E. Forest, of New York; and D. B. Simmons, of Poughkeepsie.

DR. A. R. SIMMONS, of Utica, read a paper on

ACUTE NEPHRITIS,

especially as following diphtheria, in which he discussed the cause and the treatment, making special reference to the germ theory.

DR. WESLEY M. CARPENTER, of New York, read a paper entitled

A CLINICAL NOTE ON ALBUMINURIA AND GLYCOSURIA,

in which he directed attention to a few clinical features present in two cases. The *first* was one which he saw in consultation with Dr. Charles H. Avery, of New York; of a woman fifty-five years of age, the mother of several children, who had been in good health up to one year previously, when she noticed that on some days she passed more than the usual quantity of urine. No other symptoms were developed until it was seen that her face was swollen under the eyes; slight swelling of the feet soon followed, with *difficulty of breathing*, and her attending physician then detected the physical signs of œdema of the lungs. The symptom which led to sending for the family physician was the rather sudden development of the difficulty of breathing. Dr. Avery examined the urine at once, and found that it contained a sufficient quantity of albumen to solidify nearly its entire bulk; the specific gravity was 1.010, and the quantity was diminished. Microscopical examination, made by Dr. Carpenter, revealed casts of nearly all varieties except blood, and in very great abundance.

A full dose of elaterium was administered, which operated freely; this was followed by the use of nitroglycerin—one drop of a one per cent. solution three times a day. The urine was examined chemically twice daily, and microscopically once a day; and at the end of two days only a trace of albumen could be detected, and it contained only a few casts. At the end of a week both albumen and casts had entirely disappeared; and at the end of two months the nitroglycerin was discontinued entirely. Examination of the urine was repeated at intervals from this time on, but with negative results.

At the end of three months it was noted that the specific gravity was above 1.020, and that the quantity had increased considerably. It was then tested with Fehling's solution, and revealed distinct evidence that it contained sugar. From that date forward, nearly two years, the patient had exhibited some of the ordinary phenomena of diabetes mellitus.

The chief points of interest in this clinical history were: first, the well-marked symptoms of kidney disease; second, their rapid disappearance under the influence of nitroglycerin; and, third, the appearance of glycosuria, which has thus far remained permanent.

Albuminuria occurs not infrequently with glycosuria, but in the case reported it seemed evident that changes existed in the kidneys far beyond a simple swollen and granular condition (Senator) of the epithelia of the uriniferous tubules.

The fact, however, that the albuminuria disappeared entirely, and that the urine has not since contained casts, favored the view that the glycosuria preceded the albuminuria.

CASE II.—In June, 1885, Dr. —— placed in his

hands an accurately recorded clinical history of his own case for one month, in which it was found that the urine contained sugar, but in general the patient had not suffered any special inconvenience on account of its presence. The interesting feature of the case pertained to the diet. The patient, immediately on discovering sugar in his urine, restricted himself to the usual diabetic diet, and the result was the prompt disappearance of sugar from the urine according to Fehling's test. The first compromise consisted in eating gluten bread, when he found that within two hours after he had taken it sugar was present in his urine. This experience seemed to agree with that obtained by a large percentage of those who had bought diabetic bread at some of the more popular establishments.

From this point the patient began to experiment with reference to his diet. He soon discovered that watermelons could be taken without being followed by sugar in the urine, and he therefore ate them very freely and with notable benefit. He also learned that he could eat raw peaches without limitation and with impunity. The doctor also discovered that the ingestion of any of the cereals, except buckwheat, was quickly followed by sugar in the urine. He has been able, during the last six months, to eat buckwheat-cakes without detriment, but recently he has noticed that their ingestion has been followed by a slight trace of sugar in the urine.

The most noteworthy fact concerning his diet is that potatoes do not produce sugar in his urine. This article has been particularly prohibited in diabetic diet-lists. Doubtless in most cases their use is detrimental.

Such cases verify the statement made by Pepper, that the governing principle is that starch and sugar should be excluded from the diet of diabetics; but, at the same time, no inflexible rule applying to every case can be made.

This patient has used the arsenite of bromine with the restricted diet, and his general condition remains good.

In connection with the examination of the urine by means of Fehling's solution, the writer of the paper directed special attention to the additional step in its application, proposed by Seegen, of Vienna, who described a method by which he claimed to be able to detect sugar in the urine when it could not be detected by the tests ordinarily made. The method has been revived by Dr. McBride, of New York, and is as follows: Take, for example, a specimen of urine from which sugar cannot be precipitated by Fehling's solution, and filter it through blood charcoal (not ordinary animal charcoal); then wash the filter with distilled water, and test the third and fourth washings with Fehling's solution, and if sugar is present it will be detected readily.

The explanation is that the urine contains certain substances which are capable of holding sugar in solution, that these substances are detained in the filter, and that by repeatedly washing the filter with water they are made to release their control over the sugar and allow it to be precipitated by the copper test.

A paper on "Tubercular Ulceration of the Vocal Cords," by Dr. J. P. Creveling, of Auburn, was read by title.

Dr. W. C. Wey, of Elmira, read a paper on

MEDICAL TESTIMONY AND THE HYPOTHETICAL QUESTION,

in which he clearly set forth the difficulties surrounding the task of securing competent medical evidence, and the embarrassments surrounding the hypothetical question. The expert medical testimony should be entirely under the supervision of the court.

The paper was discussed by Dr. Sherman, of Ogdensburg.

Dr. W. B. Chase, of Brooklyn, read a paper on

ANTISEPTICS IN MIDWIFERY,

the first portion of which referred to the germ theory, its general acceptance, the extreme views which have been held by foreign and American writers on the subject, and the second part considered the practical application of the accepted antiseptic principles before confinement, during and after labor.

A paper on "Ozena," by Dr. J. O. Roe, of Rochester, was read by title.

Dr. Lucien Howe, of Buffalo, made a communication on

[illegible] PLANTATION OF THE [illegible]-BALL,

and exhibited the rabbit upon whom he had performed the operation three days ago. The cornea was comparatively clear, and the iris was visible, and there was only slight conjunctival inflammation. But the cornea always sloughs, and the globe also, but the operation shows that a slight amount of circulation is established in the globe.

The paper was discussed by Drs. H. D. Noyes and W. F. Mittendorf, of New York, and Dr. Baker, of Niagara.

Dr. E. L. Keyes, of New York, read a paper on

THE RADICAL TREATMENT OF HYDROCELE AND VARICOCELE

by means of subcutaneous ligation of the veins in varicocele with carbolized catgut, which in his hands has uniformly been successful. Etherization is not admissible, because the patient must stand up, and he has used both straight and curved needles.

For hydrocele he uses pure carbolic acid by injection, suggested by Dr. Levis, of Philadelphia, with a glass syringe having an ordinary hypodermic point; first withdrawing the fluid, and then throwing in pure carbolic acid deliquesced with a few drops of glycerine—one drachm.

Dr. Weir, of New York, spoke of the caution necessary in the use of more than one drachm of the acid for a single injection in hydrocele. He had used the subcutaneous ligation for varicocele in twenty-two cases, with six unsatisfactory results. For small varicocele this method is the best; but for the large he truncates the scrotum, and ties the veins in one or two places.

Dr. Gerster, of New York, added his testimony to Dr. Weir's in the treatment of small varicocele, but for the large he favored complete exposure of the parts to be operated upon under antiseptic precautions.

Dr. Pease, of Syracuse, saw no reason why Dr. Keyes' method was not as applicable to large as to small varicocele.

The discussion was closed by Dr. Keyes.

Dr. Whitbeck, of Rochester, reported a case of

PELVIC ABSCESS

which illustrated the importance of drainage.

Dr. V. P. Gibney, of New York, read a paper on

THE MANAGEMENT OF CLUB FOOT,

in which he considered the abuse of tenotomy, the advantages of early treatment, how the mother may intelligently co-operate with the medical attendant, the delusion of "rapid cure," the value of plaster-of-Paris as an adjuvant, and also the extensive surgical operations sometimes adopted. The paper was discussed by Drs. M. Josiah Roberts, of New York, and A. M. Phelps, of Chateaugay.

The Society then adjourned to meet at 2.30 P.M.

AFTERNOON SESSION.

The Society was called to order at 2.30 P.M. by Dr. W. C. Wey, of Elmira.

The Committee reported the following

INVITED GUESTS.

Drs. E. A. Bartlett, John Thompson, U. B. La Moure, and H. S. Case, of Albany; A. A. Christie Perry, of Steuben County; L. D. Bulkley, of New York; L. E.

Blair, W. B. Sabine, Henry Lilienthal, Theodore P. Bailey; H. H. Fish, of Mecklenberg, Schuyler County.

REPORT OF COMMITTEE ON PRESIDENT'S ADDRESS.

Dr. F. R. Sturgis, of New York, read the report, which recommended, concerning increase in permanent membership, that hereafter, and immediately prior to the reading of papers at the sessions of the annual meeting, the names of those who are eligible to permanent membership by reason of having served three years as delegates, and who have signified their desire to become members, shall be read to the Society, and if objection is made to any applicant the case shall be referred for final adjudication to the Committee on Ethics; that no change in place of holding the annual meeting should be made; that it had no recommendation concerning honorary degree in medicine to be conferred by the Regents; that earnest honest efforts be made to secure the passage of the bill creating a State Board of Medical Examiners.

The report was adopted.

The report of the Committee on a communication from the New Jersey Medical Society, Dr. S. O. Vander Poel, of New York, Chairman, was read and referred. It related to preliminary education of medical students.

The Auditing Committee reported that the Treasurer's accounts and vouchers had been found correct.

Dr. R. F. Weir, of New York, then read a paper on

ANTISEPTIC IRRIGATION OF JOINTS FOR SEROUS SYNOVITIS,

and gave cases illustrating the value of this method.

The paper was discussed by Drs. Gerster and Gibney, of New York, and Dr. Hailes, of Albany.

TERM AND NUMBER OF DELEGATES.

Dr. C. H. Porter, of Albany, introduced a resolution which provided that the President should appoint a committee of three to report at the next meeting what, if any, changes should be made with reference to the number and length of term of delegates from county societies and other organizations.

Dr. Wm. Hailes, Jr., of Albany, read a paper entitled

BACTERIA: IDENTIFICATION AND CLASSIFICATION OF SPECIES,

as especially observed in his analyses of water.

Dr. W. F. Mittendorf, of New York, reported a case in which he removed with forceps

A PIECE OF IRON FROM THE EYE,

after making an opening opposite to the point of entrance.

Dr. Roosa, of New York, thought that with the brilliant result of this case we should reaffirm that the danger of sympathetic inflammation is not removed when the foreign body is taken away.

Dr. H. D. Noyes, of New York, gave his experience briefly in a number of these cases, in which he endeavored to remove the foreign body by means of the magnet. The eyeball can be saved, in some cases vision spared, and not in all cases do conditions follow which render enucleation necessary.

Dr. Maurice Perkins, of Schenectady, with reference to

STATE LOCAL HEALTH BOARDS,

believed that the civil service principles should be applied.

INVITED GUESTS.

Drs. F. N. Otis, of New York; Frank Merrington, John McAllister, James Mitchell, and William Shutter, of Albany.

Dr. L. D. Bulkley, of New York, read a paper on

NON-VENEREAL SYPHILIS,

referring to the cases in which the disease has been communicated by methods other than sexual intercourse.

Dr. F. N. Otis, of New York, read a paper on

THE LIMITATION OF THE CONTAGIOUS PERIOD OF SYPHILIS IN RELATION TO MARRIAGE, ETC.

According to the views entertained by the author of the paper there is no such thing, strictly speaking, as hereditary transmission of syphilis; that there is no well-authenticated evidence of communication of syphilis after the secondary stage has been completely passed; that after the absence of all symptoms referable to syphilis for one year, marriage can be entered into with safety; that communication of syphilis after the third year of its existence is rare; that tertiary syphilis is due to obstructive changes affecting the lymph-channels caused by the disease in its secondary stage; that spontaneous recovery from tertiary syphilis may occur, etc.

Dr. D. H. Goodwillie, of New York, read a paper on

THE TREATMENT OF TERTIARY SYPHILIS OF THE NOSE, MOUTH, AND THROAT,

making special reference to removal of necrosed bone by means of the revolving knives. A large number of wax models were exhibited illustrating cases successfully treated.

These papers were discussed by Drs. Sturgis, P. A. Morrow, and Jacobi, of New York, who criticised most of the points brought forward by Dr. Otis, who closed the discussion and further defended his position on this subject.

Dr. Bulkley, in closing the discussion on his paper, also criticised Dr. Otis' views.

Dr. Agnew, of New York, gave a synopsis of his paper

ON HYGIENE OF THE EAR,

in which he had collected 2,844 cases of consecutive diseases of the ear, and of which 2,183 were of the middle ear, 6 of the auricle, 362 of the auditory canal, 15 of the mastoid alone, 244 of the labyrinth, and 34 unclassified. The important etiological factor in the middle-ear cases was naso-pharyngeal diseases.

The President appointed as special committee on Dr. Porter's resolution: Dr. Charles H. Porter, of Albany, Chairman, Dr. W. C. Wey, of Elmira, and Dr. D. B. St. John Roosa, of New York.

The Society then adjourned to meet at 9.30 A.M. on Thursday.

Evening Session.

The Society convened in the Assembly Chamber and listened to the annual address of the President, for which he was tendered a vote of thanks. Subsequent to the address a banquet was given at the Delavan House which was largely attended.

Third Day—Thursday, February 4th.

The Society was called to order at 9.30 A.M. by The President.

Prayer was offered by Rev. Father Edward A. Terry. Dr. H. B. Conrad, of New York, was present as an invited guest.

Dr. F. C. Curtis, of Albany, presented the report of the Committee on Hygiene, and asked the individual support of members throughout the State in the work formulated by Dr. Stoddard, of Rochester, Chairman. The report of the Committee on Experimental Medicine was accepted.

Committee on Publication presented its report, which was adopted.

The Secretary acknowledged the receipt of a communication from the State Department at Washington concerning cholera.

The resignations of Drs. John Ordronaux and E. R. Squibb were accepted with regret.

Dr. D. B. Simmons, of Poughkeepsie, read a paper on

LEPROSY IN JAPAN,

in which he spoke of its distribution, prevention, clinical history, and treatment. He rejects the germ theory of its origin.

The paper was discussed by Dr. A. N. Bell, of Brooklyn.

The following papers were read by title and referred: "Abscess of the Liver," by Dr. B. C. Senton, of Whitehall; "Pin Operation for Deviated Septum," by Dr. W. C. Phillips, of New York; "Early Operations," by Dr. T. H. Squire, of Elmira.

Dr. W. H. Bailey, of Albany, read a practical and valuable paper on

HEMORRHOIDS IN PREGNANCY.

Discussed by Dr. W. S. Ely, of Rochester, who spoke of the benefit derived from upward elastic pressure by rubber bandage.

Dr. W. H. Thomson, of New York, read an elaborate paper on

PREVENTION OF HEMIPLEGIA,

and discussed the predisposing causes of arterial degeneration, heredity, influence of diet, and effect of climate.

Dr. F. C. Curtis, of Albany, read an interesting paper on

RINGWORM OF THE SCALP IN ASYLUMS AND PRIVATE PRACTICE,

and recommended chrysophanic acid in its treatment.

The paper was discussed by Dr. F. R. Sturgis, of New York

Drs. Charles Cary, of Buffalo, and W. M. McLaury, of New York, read papers in favor of cremation, which were discussed by Dr. D. B. Simmons.

A paper on "Excision of the Knee-joint," by Dr. A. M. Phelps, of Chateaugay, was read by title.

REPORT OF THE COMMITTEE ON NOMINATION.

Dr. S. Oakley Vander Poel, chairman; Lawrence Johnson, secretary.

President—William S. Ely, of Rochester.

Vice-President—Solomon Van Etten, of Port Jervis.

Secretary—William Manlius Smith, of Syracuse.

Treasurer—Charles H. Porter, of Albany.

Censors—Southern District: John S. Warren, of New York; Walter B. Chase, of Kings; E. T. Brush, of Westchester. Eastern District: Joseph Lewi, of Albany; Thompson Burton, of Montgomery; Leroy McLean, of Rensselaer. Middle District: Lansing Griffin, of Broome; Robert Frazier, of Oneida; I. N. Goff, of Madison. Western District: Theodore Dimon, of Cayuga; M. S. Gittinger, of Niagara; David Little, of Monroe. Medical College, Syracuse University: John Gerin, of Cayuga.

Committee of Arrangements—S. B. Ward, of Albany; E. L. Partridge, of New York; W. E. Ford, of Utica.

Committee on By-laws—W. C. Wey, of Elmira; H. G. Piffard, of New York; William Manlius Smith, of Syracuse.

Committee on Hygiene—E. V. Stoddard, of Monroe; F. C. Curtis, of Albany; A. N. Bell, of Kings; R. Loughran, of Ulster; J. P. Creveling, of Cayuga; E. Hutchinson, of Oneida; W. H. Bailey, of Albany.

Committee on Legislation—F. R. S. Drake, Laurence Johnson, and D. B. St. John Roosa, of New York.

Committee on Medical Ethics—A. Jacobi, of New York; Arthur Matthewson, of Kings; J. W. Whitbeck, of Monroe.

Committee on Prize Essays—George F. Shrady, Frank P. Foster, and Wesley M. Carpenter, of New York.

Committee on Publication—William Manlius Smith, Charles H. Porter, Alfred Merce, J. O. Roe.

Honorary Members—Lawson Tait, of Birmingham, England; E. N. Brush and J. G. Richardson, of Philadelphia; T. Hansen, of Copenhagen.

Delegates.—Canadian Medical Association: B. F. Sherman, of St. Lawrence; Albert Vander Veer, of Albany; W. W. Potter, of Erie; A. M. Phelps, of Franklin. Connecticut Medical Society: F. A. Castle, of New York; E. M. Hermance, of West Chester; C. E. Willard, of Greene County. New Jersey Medical Society: P. R. Furbeck, of Fulton; J. P. Creveling, of Cayuga; J. C. Hutchison, of Rensselaer. Ontario Medical Association: L. Howe, of Erie; F. Henkel, of Erie. Pennsylvania Medical Society: C. R. Agnew, of New York; Solomon Van Etten, of Orange. Vermont Medical Society: F. S. Low, of Oswego; W. O. Moore, of New York; Thompson Burton, of Montgomery. Massachusetts State Medical Society: E. H. Parker, of Dutchess; H. G. P. Spencer, of Jefferson.

Eligible to Honorary Membership.—J. A. S. Grant Bey, of Cairo, Egypt; Duane B. Simmons, of Poughkeepsie; Professor Fenwick, of Montreal, Canada.

Delegate to German Surgical Congress.—A. M. Phelps, of Franklin County, also delegate to British Medical Association.

Dr. S. B. Ward, of Albany, introduced resolutions of thanks to the President and Custodians of the City Hall, with substantial remembrance of the janitor, and to the railroads for reduction in fares, which were unanimously adopted.

INVITED GUESTS.

Drs. C. E. Annabel, of Cameron; C. E. Bruce, of New York; P. J. Keegan, Lewis Balch, and A. B. Huested, of Albany; S. S. Wallian, and F. D. Fisher, of New York.

Dr. J. P. Boyd, of Albany, read a paper on "Hemorrhage after Removal of Cervix Uteri with Galvano-cautery Wire."

Dr. F. S. Crego, of Buffalo, read a paper on "Migraine."

Dr. F. W. Hinkel, of Buffalo, read a paper on "Tubercular Ulceration of the Pharynx."

Dr. F. Petersen, of Poughkeepsie, read a paper on "A General System of Districting the State Asylums for the Accommodation of the Acute and Chronic Insane."

Dr. F. N. Hamlin, of Auburn, read a paper on "The Emission of Semen as a Means of Diagnosis of Death by Hanging."

Dr. A. B. Huested, of Albany, read a paper on "The Benefits arising from Laws Regulating Pharmacy."

Dr. S. S. Wallian, of New York, read a paper on "The Bacillus Ethicus Medicinalis."

The following papers were read by title: "Well-water in its Relation to Microspores," by Dr. F. E. Martendale; "The Free Dispensary System," by Dr. J. W. Howe, of New York; "The Treatment of Epilepsy," by Dr. C. L. Dana, of New York; "Ozæna," by Dr. J. O. Roe, Rochester.

The Society then adjourned.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Stated Meeting, January 11, 1886.

STEPHEN SMITH, M.D., CHAIRMAN.

DIAGNOSIS AND TREATMENT OF INTRA-PERITONEAL WOUNDS OF THE URINARY BLADDER—THE LANCET OF ANÆSTHETICS IN CHRONIC BRIGHT'S DISEASE.

The Chairman introduced the first subject for discussion by stating that it was closely related to the subject before the Section at its last meeting, viz., "Laparotomy in Penetrating Wounds of the Abdomen." Although intra-peritoneal wounds of the urinary bladder are not very uncommon, there being somewhat over two hundred cases on record, there is no settled method of treatment. It was true, he stated, that all methods of treat-

ment had failed, as there now seemed to be but one well authenticated case of recovery on record, and on this account it was all the more important to determine upon a method of procedure which would rescue this accident from the category of fatal injuries. Dr. Stein, who has investigated the subject, and written a valuable memoir, will commence the discussion.

Dr. Alexander W. Stein continued the discussion (see p. 146).

Dr. Seneca D. Powell said he had seen one or two cases where the bladder was injured. He was present at the time when the man's bladder was ruptured in Bellevue Hospital, in the case to which Dr. Stein had referred. In that instance the organ was very much distended. A consultation was called of the house staff, and it was determined to perform external urethrotomy without a guide, though the opinion of some was that it would be better to tap the bladder through the rectum before administering the anæsthetic. The patient took ether very badly, and during his struggles it was noticed that the abdomen assumed a flat appearance, and that the pulse quickly became accelerated. Nothing was done beyond the operation of external urethrotomy. The bladder was empty, and the man died within a few hours. The post-mortem showed that the rupture took place in the upper and posterior portion of the viscus.

In the other two cases which he had seen the bladder was injured during the operation of laparotomy. In one case, which occurred only a few months ago, the bladder was drawn up by old adhesions. The other case occurred one or two years ago. The incision in both instances was about one inch long, and the opening in the bladder was closed by carbolized silk sutures, the stitches being passed through the entire coats of the bladder and secured in the edges of the abdominal incision. The laparotomy was discontinued. The patient recovered. Laparotomy was performed successfully at a later period by making the incision to one side of the median line and thus avoiding the bladder. He saw no reason, although he had had no experience, why we should hesitate, with our present knowledge of abdominal surgery, to open the abdomen and wash it out and sew up the laceration in the bladder. He thought if this operation could have been performed on the patient in Bellevue Hospital, that he would have had a fair chance of recovery, because it would have been done so soon after the occurrence of the injury.

In neither of the cases of laparotomy was urine admitted into the abdominal cavity.

Dr. A. Jacobi said that he had had no experience whatever on the subject, but there were some remarks in the paper which might bear a little discussion. One was the fact that a great many ruptures had taken place, not in a normal or in an atrophied bladder, but in hypertrophied bladders. Now, hypertrophy means in every viscus not exactly an increase of the normal tissue, which certainly would resist rupture better than the normal bladder, but it means hypertrophy produced by abnormal tissue. Thus we see hypertrophy in the bladder, after stricture, by over-exercise of the organ and secondary cystitis. We see it also in other cases of more or less primary or secondary cystitis. So it is true that the wall of the bladder, when it is opened, is very thick, the thickness being due, however, not to normal tissue, but to tissue changed by inflammatory process, and muscular tissue always in a condition of degeneration. Thus it is, as Dr. Stein has mentioned, we see rupture taking place in such hypertrophy of the bladder. In the same way rupture of the heart will take place more frequently in so-called hypertrophy, the result of old general myocarditis. There is thickening of the wall of the heart, but the thickness is produced by inflammation and granular degeneration of the muscular tissue, and there it is where the heart will rupture.

It was a question with him whether anybody would be found who would execute what Dr. Stein had proposed as possible, namely, making an incision into the peritoneum and reaching the bladder from that side. It was true that drainage could be established, but there would be no way of washing the urine out thoroughly and finally healing up the wound. As far as the latter was concerned, he would like to ask to what extent sutures in the bladder were well tolerated. Inasmuch as the experience of olden times, that of the period preceding modern antisepsis, might be regarded as of little importance, he hesitated to report a case; but otherwise he would like to lay some stress upon an operation at which he was present about twenty years ago, where the late Dr. Krackowizer performed pubo-cystotomy in such a way that the peritoneum above the symphysis pubis was not touched. The bladder was entered and the calculus removed. The late Dr. Sims was present, and it was only a short time after he had brought forward the merits of the silver-wire suture, and he suggested, in opposition to Dr. Krackowizer, who had expected to leave the wound open, the propriety of sewing up the opening in the bladder with silver wire. Dr. Krackowizer consented, and Dr. Sims applied the sutures. Dr. Jacobi believed that in consequence of the more protracted operation, perhaps in consequence of some irritation which was not attended with antisepsis, the patient died. As a rule, we do not expect patients to die on whom the high operation has been performed.

The next point which suggested itself to him while listening to Dr. Stein's excellent paper was this, the symptomatology of some of the cases is not always clear. Several modes of examination appear to give insufficient results; for instance, the introduction of the catheter into the bladder. The very fact that the catheter can be introduced into the bladder very high up does not prove that it is outside of the organ. He had seen a few instances in which there was no question at all, where he could feel the catheter in the neighborhood of the liver, and still it was within the viscus. In these cases there were congenital anomalies. In one instance he had to deal with the bladder in connection with an unclosed urachus, and the bladder extended all the way up to the umbilicus. Such a case might easily give the impression that the end of the instrument was outside of the bladder.

Another case was the following: A child, three or four years of age, had a tumor in the abdominal cavity. That tumor was in the median line, and extended as high as the region of the umbilicus, and it had two horns. There was also a depression in the median line, and at both sides the tumor extended pretty high up. It looked, therefore, like a bicorned uterus. Several diagnoses had been made, such as ovarian cyst, echinococcus, etc. But when he had the child under the influence of chloroform, for the purpose of examination, he found that he had to deal with the peculiar anomaly of a bicorned bladder, which extended far up to the left and to the right, with a little depression in the median line, with a very thin wall, and that when the urine flowed off entirely the tumor coincidently disappeared. In such exceptional cases one can very easily mistake about this symptom, the obscurity and insignificance of which Dr. Stein himself had emphasized. Dr. Jacobi asked if there was any particular danger in suturing the bladder.

Dr. Alfred C. Post said it had been done a number of times, and also successfully in a number of cases. The gynecologists were in the habit of sewing up the bladder in vesico-vaginal fistula, and their wounds united well. He remembered a case in which an operation for stone was performed through the rectum and the stone extracted, and the vesico-rectal wall sutured with success. He was unable to recall the name of the writer of the paper in which this case had been reported. He thought that in several cases of ovariotomy the bladder had been injured, and that sutures had been applied with success. If he remembered correctly, Dr. Thomas had reported one such case.

The Chairman said that so far as suturing the bladder

was concerned the wounds had shown a very decided disposition to heal, and he saw no reason why the wounds should not be sutured, and why the surgeon should not go even so far as Dr. Stein had recommended, and incise the edges so as to give clean-cut, smooth surfaces to be brought into apposition.

Dr. H. Griswold remarked that if the mucous membrane was not included in the sutures he thought there would be no difficulty in obtaining union.

The Chairman said it was a fact that in many cases of rupture of the bladder, where the patient had lived several days, there had been a decided effort at union of the wound, the urine being constantly drawn off and the edges of the wound simply being allowed to lie in contact. In some instances the wound had been entirely closed, especially where the urine had accumulated behind the bladder in the cavity of the pelvis, and the inflammation had been such as had circumscribed it, and there was no general peritonitis. In some of these cases the wound had been entirely healed.

Dr. Jacobi said this might occur the same as it might take place in the uterus after Cesarean section; the wound healing as the parts were in juxtaposition.

The Chairman remarked that there must be some difficulty in suturing wounds of the bladder, because the bladder might disappear under the symphysis. He had known of two cases of rupture of the bladder, occurring in the practice of country physicians, and in each the bladder had entirely disappeared, and had been found under the symphysis. In one case, of which he knew personally, the physician in his search was unable to discover the bladder, and reported it as one in which the organ had been entirely absorbed. The bladder had so thoroughly disappeared under the symphysis that it required a little search to find it, but it was finally found, and the rupture could be clearly made out. The Chairman would ask Dr. Post's opinion concerning the value of perineal section in these cases, which had been insisted upon by some writers as the best method of draining the bladder.

Dr. Post said it would drain the bladder more perfectly than could be done with a catheter. The introduction of a tube through the perineum would cause less irritation than would be produced by the introduction of a tube through the entire urethra, and, with reference to drainage, it would give more perfect drainage, because a short, straight instrument could be used, and no muscular effort would be required to effectually empty the bladder.

The Chairman closed the discussion, remarking that the diagnosis of intra-peritoneal wounds was sometimes very easy, and again it might be very difficult. In general there is evidence of a full bladder, shock, inability to walk, desire to urinate without being able, great pain in the hypogastric region, discharge of bloody urine through the catheter, and occasionally the passage of the catheter through the rent. But these symptoms may vary very much, or, for the most part, be absent. In one case a surgeon fell from a horse, and was so slightly injured that in the evening he attended a dinner-party, where he related the accident to another surgeon, who stated that the symptoms indicated rupture of the bladder, which proved to be true, as he died in forty-eight hours.

The ability of the patient to urinate voluntarily has frequently been demonstrated. The true indications of treatment have long been recognized, viz., drainage of the urine from the bladder as fast as it is secreted, and removal of the urine from the peritoneal cavity. In general the catheter retained in the bladder is relied on for drainage, but it cannot be relied on implicitly. Opening the urethra as in perineal urethrotomy has been advised. But a more effectual drainage is secured by incising the neck of the bladder as in lateral lithotomy. This operation was recommended by him in a paper published in 1851, in which was reported a successful case of lateral cystotomy for rupture of the anterior walls by Walker, of Massachusetts. Mason repeated the operation successfully. The advantages are evidently due to the paralysis of the neck of the bladder, and the direct drainage from the base of the bladder, so that no accumulation can occur. It has been proposed to siphon the bladder, but no result has yet been obtained by this method. The removal of the urine from the cavity of the peritoneum has been accomplished in various ways. In the first reported case by Bonetus, paracentesis was performed, but without success. Blundell, the obstetrician, recommended in 1825, sixty years ago, the opening of the cavity of the peritoneum, and the thorough ablution of the abdominal cavity and its contents by means of the free injection of *distilled* water at 98° F. or more. The operation, he says, should be continued prudently, no symptoms forbidding, till the water comes away without manifesting the urinary characteristics. This method of cleansing the peritoneal cavity is not unlike that now advised by Mr. Tait. He also advised that, after cleansing the abdominal cavity, the ruptured part should be drawn up to the abdominal opening, the laceration closed with a ligature, the parts beyond the ligature cut away, one end of the ligature cut, and the other brought out of the wound. With the exception of providing drainage from the bladder, Blundell thus early met the indications of treatment. In the only case of undoubted intra-peritoneal rupture which recovered, the means employed was, cleansing the peritoneal cavity and the drainage of the bladder by the catheter. The closure of the wound of the bladder does not seem, therefore, to be a necessary part of the treatment when drainage is satisfactory. There is no doubt that when the urine is constantly drained away, the bladder remains so firmly contracted that the edges are in proper contact for union. Still, there can be no objection to closing the vesical wound with suture, and if there is doubt about the drainage the wound should be closed of necessity. In regard to the best method of securing the escape of the urine as fast as secreted, he believed that incision of the neck of the bladder by lateral cystotomy was the most certain. He had recommended this method in a paper which he published in 1851, embracing notes of seventy-eight cases, and it had been performed by several surgeons with satisfactory results as regards drainage, and with recovery in at least three cases. He had operated in one case of perforation of the bladder by a foreign body; the drainage was perfect; the patient died twenty-four hours after of other injuries, and the bladder was found firmly contracted and empty. Perineal urethrotomy is no substitute for cystotomy, as the neck of the bladder retains its power of obstructing the flow of urine. The use of the ordinary catheter cannot be relied on, as it does not entirely evacuate the bladder with certainty; if retained, it becomes a source of irritation; if used at intervals, it does not prevent accumulations of urine which may escape through the wound, and which, at any rate, must cause contraction of the bladder, and thus prevent that complete rest essential to the rapid closure of the wound. If a catheter is employed for drainage, it should be the soft, velvet-eyed instrument, and be introduced just within the neck, so that the internal end rests on the base of the viscus. The proposition to siphon the bladder with one of these catheters, the external end being submerged and the catheter firmly fixed so that the eye of the instrument constantly rests on the base of the bladder, would seem to fulfil the indications well. He would summarize the course of treatment that would most effectually meet the indications as follows: 1, Laparotomy and thorough cleansing of the peritoneal cavity, especial attention being given to the pelvic cavity and the convolutions of the intestines; 2, suturing of the wound in the bladder, if it can be readily effected; 3, lateral cystotomy, or efficient syphonage of the bladder.

Dr. H. Griswold asked the Chairman if he had found that perfectly fresh urine produced much irritation of raw surfaces. He had found that, in operating for rupture of

the perineum, fresh urine did not irritate the wound very much.

The Chairman said it was a fact that the peritoneum in different persons and under different circumstances was much more readily irritated in one than in another. Whether the tolerance in some patients was due to change in the character of the urine was not always plain.

Dr. Post asked if the extravasation of urine into the peritoneal cavity, although it might be immediately washed out, would not probably prove a source of very greatdanger to the patient.

The Chairman replied probably not. The great difficulty was that patients did not have the benefit of medical attendance when the rupture occurred, and sometimes it was a matter of several hours, or even days, before surgical assistance could be obtained.

Dr. Wesley M. Carpenter read a paper (see p. 144) on

THE INFLUENCE OF CHRONIC BRIGHT'S DISEASE ON THE SAFETY OF ANÆSTHETICS.

Dr. Post referred to an operation which he saw performed by Dr. Bangs, at St. Luke's—a circumcision on a boy about ten years of age. The orifice of the prepuce was very small, scarcely admitting a probe. This patient had about five per cent. albumin in his urine, and, because of that, extraordinary care was taken in administering the anæsthetic. Respiration was not as good as usual, but the patient got through the operation safely. The question was raised at the time concerning the extraordinary care required in the administration of the anæsthetic on account of the kidneys not being in a sound condition. He had not met with a fatal case under the same circumstances.

Dr. S. D. Powell had seen one patient die after the administration of ether, and the autopsy showed disease of the kidneys. The patient was in the service of Dr. Hamilton, in Bellevue Hospital. He had, on several occasions, seen patients pass into a comatose condition after an operation, sometimes very slight, on the genito-urinary tract, and he had thought the condition was produced by the shock and not by the anæsthetic. He recalled one case occurring in the practice of the late Dr. James L. Little, where, without an anæsthetic, the passing of a catheter brought on, within one or two hours, coma, and it was only by the greatest care and attention that the patient's life was saved. There was a slight quantity of albumin in his urine, but no casts. He had thought that operations on the genito-urinary tract were more frequently followed by shock than operations upon other parts of the body, and had always looked toward the condition of the kidneys, no matter how simple the operation might be. He was inclined to attribute the condition to shock, combined with disease of the kidneys, rather than to the influence of the anæsthetic or the administration of ether.

Dr. A. Jacobi said the entire subject was certainly a very vast one, and therefore only a few remarks would be justified at that time. When there is albuminuria, with some form of so-called Bright's disease, danger arises from several causes. Patients may die from real uræmia; frequently they die from anæmia, and now and then of anæmia and œdema of the brain. Even in such cases where the large blood-vessels are very much filled, in fact the more they are filled the more apt they are to compress the brain tissue, and, therefore, while such a condition looks like one of hyperæmia, it is really one of anæmia. Thus in many of these cases the patient appears to die of actual anæmia. In one of the cases reported by Dr. Carpenter the patient certainly died of anæmia of the brain. There was stenosis of the aorta, and consequent insufficient supply of blood to the entire body. That man was operated upon, did fairly well, and yet eight hours after the operation he had left his bed and been to the water-closet, and it seemed to him that the fatal result was due to anæmia of the brain, as patients were seen dying occasionally in this manner. He recalled a case of pneumonia occurring in a middle-aged man, and the patient was warned against getting up, but he did get up, went through the room, sat down upon the water-closet, started to go back to bed, fainted on the way, and was soon dead. He had seen many such cases in children who had not suffered from chronic kidney trouble; and also quite a number of children who had been taken very suddenly from bed after suffering from a protracted illness, and in consequence had died suddenly.

The second case reported by Dr. Carpenter, therefore, appeared to him to have terminated fatally from anæmia of the brain, perhaps influenced by the ether; at all events due to the atheromatous condition of the arteries, which resulted in the insufficient supply of blood. In cases in which persons have a slight amount of albumin in the urine, and in middle-aged persons, or persons in advanced life, with or without perceptible heart disease, there exists frequently very well-marked nephritis, extending through both kidneys, resulting from exactly the condition of things which Dr. Carpenter has described; namely, atheromatous changes in the aorta and arteries in general. We should not forget one thing—namely, that when we reach middle life and have blood-vessels fully developed, from that time on, perhaps past thirty-five years of age, what might almost be called a normal atheromatous degeneration begins. Thus it is that between forty and fifty years of age so many persons die of apoplexy, the result of rupture of cerebral blood-vessels. It is the rule for every middle-aged man to have an atheromatous condition of the arteries; usually in the smallest arteries, sometimes in the largest ones, as has been described. Thus it is that the large majority of brain cases, occurring as such, will be explained by the anomalous condition of its arteries.

Now, when we come to speak of cases of heart disease with nephritis, it is not always easy to say whether the heart disease is the result of the kidney disease, or whether the heart and kidney disease are the result of one and the same general condition; that is, a general, almost normal, atheromatous degeneration of the blood-vessels. These cases of Bright's disease are sometimes those in which we find no albumin whatever; in most cases we find only a trifling amount of albumin. Still, there is nephritis which is progressive, and finally will prove fatal. When we know that all persons above middle age are no longer absolutely normal, that the arteries of the body are in the process of atheromatous degeneration, we need not wonder that anæsthetics may prove unfavorable.

Dr. Jacobi then spoke of the theory of the cause of death in chloroform narcosis as presented by Nélaton and Sims, namely, the production of sudden anæmia of the brain, and the method of counteracting it by lowering the head in order to favor an increased supply of blood to the brain. Although this theory did not hold in all cases, both the observation and the treatment were excellent. Thus it was that very often we should look to nothing more than the condition of the heart, as the reader of the paper had said, and it is very fortunate that many conditions of the heart can be detected.

The Chairman said that in Bellevue Hospital the rule was always to test the urine of every patient who was likely to have an operation.

The Section then adjourned.

Antipyrin in Acute Articular Rheumatism.—Neumann has employed antipyrin, in six or eight hourly doses of fifteen grains each, in the treatment of rheumatism, and believes that it possesses virtues equal to those of salicylic acid. He even prefers it to the latter drug in many cases, as the poisonous effects sometimes observed after the use of salicylic acid are, he says, never observed when antipyrin is employed.

Correspondence.

OUR PARIS LETTER.

[illegible]

A CASE OF HYDROPHOBIA—HOSPITAL STATISTICS—SIMULTANEOUS ADMINISTRATION OF BELLADONNA AND IODIDE OF POTASH.

[illegible]

Dr. Dujardin-Beaumetz lately read his report at the Council of Public Hygiene of a fatal case of hydrophobia that occurred at Colombes, situated just outside Paris, after a period of incubation of nineteen months. This appears to be the first authentic case on record, at least in this country, of rabies manifesting itself so long after the subject had been bitten. According to the report, the patient, who was twenty-six years of age, was slightly bitten in March, 1884, in the right hand, by a dog that did not seem to labor under any rabic symptoms. It was nevertheless killed, but no autopsy of the animal was made. Although the subject bitten entertained no fears about himself, yet he had the wound painted with the tincture of iodine and thought no more of the incident. On November 1st last, feeling some pain in the site of the wound, he consulted his doctor, who expressed his fears to the family as to the case being one of incipient hydrophobia. The doctor immediately communicated the circumstance to M. Pasteur, and called on him the next day to consult him on the subject, but the learned biologist said he could do nothing for the patient, adding: "I can preserve, but I do not cure." The symptoms of hydrophobia set in rather insidiously. On the 5th they became quite characteristic, and were accompanied by symptoms of paralysis—a rare complication in the human subject. On the night of the 7th delirium set in, and he expired in the most terrible agony. This case is interesting in many respects. In the first place, the unusual length of the period of incubation, though the physician who treated the patient under notice had met another case of fourteen months' incubation. 2. It shows the absolute insufficiency of the slight cauterization with the tincture of iodine. The red-hot iron would probably have prevented the introduction of the virus into the system. 3. The duration of the manifestations of hydrophobia: one entire week, from Saturday, October 31st, to Saturday, November 7th. According to Trousseau, death takes place in man constantly in the four days which follow the difficulty of swallowing liquids. 4. The setting in of pain in the right arm a week before the appearance of the rabic symptoms. It must be remembered that the bite was inflicted in the right hand. This case also proves that a person bitten by a mad dog from eight, ten, twelve months, and more, cannot be considered safe against the malady, and that perhaps the method of preventive inoculation as practised by M. Pasteur may still be applicable to such cases.

Apropos of the duration of the period of incubation, Dr. Dujardin-Beaumetz brought to the notice of the Council of Hygiene that since 1881 he was able to establish an average period of incubation of from three to four months in fifty-eight cases of human rabies that have occurred since that period.

You lately referred to the statistics of the hospitals of the United States. Perhaps a short account of those of the hospitals of France, which I extract from the official report just issued from the office of the Minister of the Interior, will be interesting to your readers. During the last ten years the annual average of admissions into the hospitals throughout the country was 410,000. In general there is a proportion of 90 per 10,000 inhabitants for the provinces alone. For Paris the proportion of patients treated in the hospitals has been 400 to 10,000 inhabitants. The average duration of treatment in provincial hospitals has been thirty-five and one-half days, for Paris it is only twenty-nine days. In classifying the average duration of treatment of the patients we find: Thirty-one days for men, forty for women, and forty-eight for children throughout the territory. As regards the issue of the results of treatment in the hospitals, there have been seventy-eight per cent. cured and nine per cent. of deaths in proportion to the number of patients treated, which would give an average proportion of nine times more cures than deaths. This is evidently a strong argument in favor of hospital establishments. The largest proportion of cures was among the men, and the smallest among the children, which may be represented thus: Eighty per cent. for men, seventy-five per cent. for women, and seventy-four per cent. for children. The mortality for the Paris hospitals alone is, like that of Vienna, one-fourth, and even one-third, of the total number of deaths of the population of these two cities; whereas in London and New York it constitutes scarcely one-sixth. There are in Paris twelve general hospitals and nine hospitals for special diseases, all containing 9,000 beds. There are also six asylums for the aged and infirm and five establishments for lunatics, containing 10,045 beds. The average cost of each patient in the Paris hospitals is about three francs per day; that for the provinces is about half that sum. Besides these establishments there is one for the "Enfants Assistés," which is a sort of a substitute for the old Foundling Asylum, the average number of admissions being 10,000 per year. The staff of the hospitals of Paris is composed of 99 physicians, 46 surgeons, 1,225 internes and externes, 18 pharmaciens, 108 internes in pharmacy, and 9 midwives (sages-femmes). The population of Paris is estimated at 2,239,928, and that of France over 30,000,000.

Dr. Aubert has lately published a short note on the advantages of the simultaneous administration of belladonna and the iodide of potassium. The author claims for this combination the prevention of iodism, which occurs in some people even in small doses of the iodide.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 24, 1886, to January 30, 1886.

Summers, John E., Colonel and Surgeon. Retired from active service, by operation of law, January 24, 1886. S. O. 20, A. G. O., January 25, 1886.

Waters, William E., Major and Surgeon. Granted leave of absence for one month and fifteen days. S. O. 5, Division of the Atlantic, January 23, 1886.

Banister, J. M., Assistant Surgeon. Ordered for temporary duty at Fort Warren, Mass. S. O. 16, Department of the East, January 23, 1886.

Hypodermatic Quinine.—Dr. S. S. Burt says in the *Quarterly Bulletin of the New York Post-Graduate Medical School*: "For those who are obliged to administer quinine subcutaneously, it is desirable that the solution should be as little irritating as possible. Lente's solution consists of bisulphate of quinine 50 grains, dilute sulphuric acid 100 mm., and carbolic acid 5 mm. to an ounce of water. He apparently did not know that the bisulphate is quite soluble in water without the addition of dilute sulphuric acid. Having made use of the following formula, I can recommend it:

℞.	Quiniæ bisulphatis	gr. lx.
	Acid. boracic	gr. ij.
	Morphiæ sulphatis	gr. ¼.
	Aquæ destil	ʒ j.

Sig.: For hypodermic use. One drachm contains seven and a half grains of quinine."

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 30, 1886 :

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
January 30, 1886.....	2	6	44	2	21	62	6	0
Deaths.								
January 30, 1886	0	1	10	1	1	32	1	0

TWENTY-EIGHT PER CENT. of imbeciles are left-handed (Dr. Ireland).

A SUGGESTION FOR THE TRANSFUSION OF BLOOD.—A St. Louis doctor cut off the tails of two lizards, and by sewing the ends of the stumps together made Siamese twins of the reptiles. Having thus demonstrated the feasibility of the operation, he suggests its utilization as a means of transfusing blood.

BOOKS BOUND IN HUMAN SKIN.—Following the example of Mr. Joseph Zaehnsdorf, who lately bound two Elzevir editions in human skin, another London binder has recently executed an order to encase a copy of Holbein's "Dance of Death" in the same material—assuredly a most appropriate covering for this work. These are the most recent instances of the use of human skin for such a purpose ; but they are far from unique, several criminals in olden days having been, after execution, despoiled of their integument in order that the book-shelves of some *connoisseur* of bindings might be enriched by the ghastly relic."

ALPHONSE KARR, one of the most charming of simple philosophers, tells us that "physicians, for a long time, applied the roots of fennel pounded with honey to the bites of mad dogs. At the end of three or four hundred years it was discovered that this had never cured anybody." For the older doctors, attributing virtues to plants based upon analogy, concluded that fennel must be an antidote to the bite of snakes, because, as Pliny says, snakes are exceedingly fond of it.

MEDICAL LIVERIES.—Writing on liveries the London *Evening Standard* says : "Some of the ways by which medical men announce their profession plainly come within the category of liveries. There are few survivors now of the old school, who always dressed in solemn black, with frock coat and deep stock, but specimens of this class are still to be met with in country places. In the towns doctors do not cultivate an eccentric style in dress, but an air of preoccupation and much learning indicates who and what they are. It is as easy to tell a doctor, as he drives through the street, as it is to distinguish a sailor or even a policeman. In his consulting-room, or at his patient's house, his personal idiosyncrasies —the familiarities he affects or which are natural to him —are seen in strong relief. He may be as bland as a deputation, or as peremptory as a police magistrate. He may flatter you into a belief in his own wisdom by appearing to concede everything to yours, or he may awe you by a dogmatic statement of opinion that makes no question of its own accuracy. There are many varieties between these types ; but types they all are, and to be classified as we classify the liveries of less learned men. There is a peculiarity about the names of doctors—particularly of specialists—which we have never been able to understand. If the physician we are advised to consult happens to be named Jones or Brown, the chances are ten to one that Providence, or some other benign agency, has given him another and more impressive name also, which forms an excellent combination with the simple patronymic. Dr. Jones is Dr. Phipps Jones ; Dr. Brown is Dr. Tibbs Brown. This sort of combination is so common—there is scarcely even a dentist without what looks like a distinguished prefix to his name—that we may be forgiven for questioning whether in all instances it dates from the baptismal font. If it does, then there is more in the doctrine of election and predestination than we have been accustomed to suppose."

STATISTICS OF THE LONDON MEDICAL CHARITIES.—From the "Classified Directory to the Metropolitan Charities" it appears that the approximate income of the 1,014 medical charities of London during the past year was £4,466,556 (above $22,000,000), of which the following are of a medical character : Nine charities for incurables, £47,348 ; three charities for idiots, £61,000 ; seventeen general hospitals, £321,930 ; eight consumption hospitals, £55,635 ; five ophthalmic hospitals, £9,399 ; three orthopædic hospitals, £5,236 ; three skin hospitals, £6,014 ; twenty-one hospitals for women and children, £64,933 ; six lying-in hospitals, £10,988 ; twenty-nine miscellaneous special hospitals, £108,470 ; thirty-three general dispensaries, £25,036 ; thirteen provident dispensaries, £10,094 ; two institutions for vaccination, £2,585 ; six institutions for surgical appliances, £14,336 ; forty-five convalescent institutions, £48,577 ; and fourteen nursing institutions, £3,030.

THE PRESERVATION OF ANATOMICAL SPECIMENS.—At one of the sessions of the Italian Medical Congress, held during September, 1885, Professor Angelo Comi, of Rome, described the method employed by him in the preservation of anatomical specimens. For producing a stony induration of organic bodies, he makes a soft paste of bichloride of mercury rubbed up in a mortar with linseed oil. Into this the substance which it is desired to preserve is put and kept for several months. At the end of this time it is removed, washed, and dried carefully, and then polished with a piece of agate. If the specimen has any cavities, these are first filled with a mixture of equal parts of finely powdered cement and bichloride of mercury. By this process the anatomical preparations acquire a stony hardness, and all their delicate lines are preserved in all the beauty and distinctness of the fresh state. When it is desired to keep the specimens soft and flexible, Professor Comi simply puts them in pure honey, the cavities being previously filled with tannin. In this way bodies may be kept perfectly fresh for several months.

THE COMMERCIAL RESULTS OF A NATIONAL MISUNDERSTANDING.—The pharmacists of the province of Galicia, in Spain, at a reunion held in October last, when the matter of the Carolines dispute was fresh, unanimously resolved to purchase no more drugs or chemical preparations from German houses, but to transfer their custom to French firms.

LOCAL APPLICATIONS OF COPAIBA IN VAGINITIS.—Dr. Baratier recommmends very highly the local use of copaiba in the treatment of various forms of vaginitis. He employs a suppository containing three-fourths grain of extract of opium and one and one-fourth drachm each of copaiba and cacao butter. One of these is passed into the vagina every second day and allowed to remain for twelve hours.

DEATH OF AN EMINENT HYDROLOGUE.—Dr. Benigno Villafranca y Alfaro, one of the most active members of the Spanish Society of Medical Hydrology, recently died at the age of fifty years. The society devoted one of its sessions to a eulogy of the deceased, and dedicated to his memory the November number of its annals.

COMMENTS ON PASTEUR'S METHOD OF TREATING HYDROPHOBIA.[1]

BY CHARLES W. DULLES, M.D.,

I HAD intended, as the notice of this meeting states, to discuss this evening the whole subject of the treatment of hydrophobia. But I have found that I could not cover so much ground at one time, and so I have decided to confine myself to that phase of the question which has been forced upon the notice of the whole world by the recent announcement of the discovery of a preventive method by M. Pasteur. If this method were trustworthy, it would eclipse anything which has ever before been accomplished in dealing with this mysterious and dreaded disorder. If, on the other hand, Pasteur's method is not to be trusted, it can only prove an obstacle to any real advance in our knowledge of a subject already too much encumbered with error.

For this reason it seems to me to be important that such a body as this should critically examine the evidence adduced in support of this method; so that if it appears to rest on a sound basis of reason and experiment we may adopt and recommend it; while, if it appears to be founded on untrustworthy experiments and unsound reasoning, we may reject and condemn it, in the interest of humanity as well as of science.

M. Pasteur's first communication on the subject of hydrophobia was made in a discussion before the Académie de Médecine, of Paris, January 18, 1881, when he announced that on December 11, 1880, he had inoculated two rabbits with saliva (or buccal mucus) from the mouth of a child supposed to have died of hydrophobia. The rabbits died in thirty-six hours, and in their blood he found a microbe in the shape of a figure 8, which he declared to be a new one, and to be the cause of a new disease (*Bull. de l'Acad. de Méd.*, January 18, 1881).

M. Colin, of Alfort, said this microbe had been described and figured ten years before, and that Pasteur should have searched for it elsewhere than in the saliva of persons dying of hydrophobia. He also said that Pasteur should have made control experiments to show that the inoculation of other sorts of saliva would not produce the so-called "new disease." To this Pasteur promptly replied with an interruption: "These experiments have been made without giving any results" (*loc. cit.*, p. 78).

Pasteur made his second communication at the meeting held the following week, January 25th, in a "Note sur la maladie nouvelle provoquée par la salive d'un enfant mort de la rage" (*Bull. de l'Acad. de Méd.*, 1881, pp. 91–130). In this communication he says that he had cultivated his new microbe and repeated his inoculation experiments with the cultivation as well as with the blood, a great number of times, the result being *always the same.*

These positive and unqualified declarations of Pasteur soon proved to be utterly erroneous. All that Colin had affirmed, and all that Pasteur had denied, was soon shown to be true. The microbe was not new; it was not peculiar to rabies; and the inoculation of other kinds of saliva, even that of a healthy adult, produced the same results. Pasteur himself had to acknowledge this in a letter dated March 22d, only eight weeks after his vehement and bitter repudiation of Colin's objection (*Bull. de l'Acad. de Méd.*, 1881, pp. 380, 381), and, as we know, his acknowledgments have been confirmed in this city by the experiments of Drs. Sternberg and Formad.

Pasteur's third communication was read May 31, 1881. It was entitled "Sur la rage," and was founded on experiments made with MM. Chamberland, Roux, and Thuillier (*Bull. de l'Acad. de Méd.*, 1881, pp. 717–719). In this communication he declared that "up to the present time the disease has not been communicated by the inoculation of the blood of those having rabies" (*loc. cit.*, p. 717).

In saying this Pasteur (who has never seemed aware of anything done by other experimenters, except a very few of his own immediate time and country) was, of course, utterly ignorant of the admirable and accurate experiments of Hertwig (published in 1828, in a supplement to Hufeland's *Journal*) in which the blood of mad dogs, rubbed into cuts made in healthy dogs, caused their death, after a typical incubation, in two instances, one of the dogs dying "fully mad." But he ought to have remembered that at the very meeting at which he had made his first essay in regard to hydrophobia, MM. Raynaud and Lannelongue made a detailed report of experiments, in which they had got their inoculating materials from the same patient which had supplied Pasteur with his, and that inoculations of the blood of a rabbit, dying after inoculation with the medulla oblongata of the child that had died of hydrophobia, killed two other rabbits, while the blood of one of these latter caused the death of a third. This, according to Pasteur's own standard of proof, constitutes a demonstration of what he calls the "virulence"—that is, the specific rabic nature of the inoculation material.

This evidence of ignorance on the part of Pasteur was followed up with an implied claim, which has grown stronger since then, that he and his assistants first considered the central nervous system as peculiarly involved and active in the development of the disease. Without discussing the value of this claim, or of the idea, it is interesting to observe that the evidence of its correctness rests upon Pasteur's statement that on inoculating the brain-substance of a mad dog upon the surface of the brain of another dog, by trephining, the symptoms of rabies appear after "a week or two," and that the dog *dies* in less than three weeks (*loc. cit.*, p. 718). Now, what Pasteur means by the "first symptoms" of rabies may perhaps be surmised from his statement in another place: "Nothing is more varied than the symptoms of rabies. Each case of rabies has, so to speak, its own peculiar ones" (*Bull. de l'Acad. de Méd.*, 1882, p. 1442); and again (speaking of rabbits), he determines the onset of the disease "by a change of temperature" (*Bull. de l'Acad. de Méd.*, 1884, p. 343). It is true that he says, in the communication of which I was speaking, that he got "sometimes dumb madness and sometimes furious madness," and that "none of the inoculations made in this way have failed;" but he omits to mention how many experiments he had made, or what proportion of them produced either form of rabies, or what he means by these terms.

The fourth communication of Pasteur in regard to hydrophobia was a paper entitled "Nouveax faits pour servir à la connaissance de la rage," in which the names

[1] Read before the Philadelphia County Medical Society, January [illegible], 1886.

of the same assistants appear, and which was read December 12, 1882, nineteen months after the last (*Bull. de l'Acad. de Méd.*, 1882, pp. 1440–1445).

In this he says that heretofore "the saliva was the only material in which the presence of the virus of rabies had been established," and that the inoculation of this was uncertain and tedious in its results. By experiment he had found that the central nervous system was the principal seat of the virus; that here the latter can be gathered in large quantity and "in a state of perfect purity," and that its inoculation on the surface of the brain causes rabies "promptly and surely." At the same time he declared that he and his assistants had "found the same advantages, with forms of rabies slightly different, in another method still more easily applicable, intravenous injection of the virus" (*loc. cit.*, p. 1441). To his assertion that the virus is found in the brain, he adds the statement that it is also found in the spinal cord, and often (note: it is only often, not always) in all parts of the cord. By inoculating either brain or cord on the surface of the brain, or by intravenous injection, rabies, he says, can be developed promptly and surely (p. 1443). By the latter method (intravenous injection) he got a rabies in which "early paralysis often occurs; fury is often absent; rabic howling is rare;" but, as a set-off to the lack of these characteristic signs of real rabies, he gravely asserts, "there is sometimes frightful itching" (!). He had also seen his animals with experimental rabies spontaneously recover; and, in some cases, seem to get well, and then have a recurrence of the disease two months afterward and die. (In passing, I may remark that such a course is diametrically opposed to all the history of this disease.)

In this communication we have also the only statement which I can recall as to the sources from which Pasteur has obtained his virus, viz., two dogs in 1880, since which time, he says, rabies had been kept up (*entretenue*) "without interruption" in his laboratory. At "different times" they had utilized dogs which had died of rabies in the Veterinary School at Alfort; and very recently they had received the head of a cow which had died on a farm "in consequence of bites received from a mad dog." It is interesting (as Pasteur says) to know that all the animals inoculated from various parts of the brain of this cow had already died of *rabies*. The sum of his experiments at this date was over two hundred, including dogs, rabbits, and sheep (*loc. cit.*, p. 1445).

Pasteur's fifth communication in regard to hydrophobia was made on February 26th, 1884 (fourteen months later), in his own name and in that of MM. Chamberland and Roux. It was entitled "Nouvelle communication sur la rage" (*Bull. de l'Acad. de Méd*, 1884, 337–344). In it he announced the theory that the difference between the form of rabies produced by intravenous inoculation and that produced by inoculation upon the surface of the brain, was due to the fact that in the former case the virus first becomes fixed and multiplies in the spinal cord. When he killed dogs at the moment of the "first symptoms of paralysis" (a most vague limit, especially when determined by such a man as Pasteur) he found that the cord, especially at the lumbar enlargement, might be "rabic" when the medulla oblongata was not yet affected (*loc. cit.*, p. 333). He claims that he had already demonstrated (we might say asserted) that the virus had its seat in the brain and cord, and that later he had found it in the nerves and in the salivary glands. The whole nervous system, he now declares, is capable of "cultivating" the rabic virus. But all his efforts to "cultivate" the virus of rabies artificially had failed.

When asked by M. Bouley if there were no *microbe* of rabies, Pasteur answered that he could only say that if shown two brains, one healthy and the other of a rabid could say from a microscopic examination: is rabic; that one is not;" adding, that "both brains would) exhibit immense numbers of molecular granules, but those of the rabic medulla are smaller and more numerous, and one is tempted to believe in a microbe of infinite smallness, having neither the shape of a bacillus nor that of a *microcoque étranglé*; they are like simple points." This very vague description of the supposed germ of hydrophobia was not even original; for M. Béchamp, of Lille, soon showed that he had already studied, and described under the name of "microzyme," what Pasteur spoke of as if *he* had first recognized it.

The next thing which attracts attention in this communication of Pasteur is the reassertion that inoculation by intravenous or hypodermic or intracellular injection is followed by paralytic rabies; coupled with the paradoxical statement that furious rabies can be produced "on the sole condition of using *very small* quantities of virus." "The less virus," he says, "employed for hypodermic or intravenous inoculations, the more readily is furious rabies obtained."

Now, in addition to the difficulty of comprehending how intravenous inoculation of small quantities of virus can produce the furious form of rabies, and larger quantities the mild form, what becomes of Pasteur's explanation of the production of the milder form by "fixation" as he calls it, of the virus in the spinal cord? If the ordinary quantities become "fixed," why do not small quantities become fixed too? Again, he says that the employment of small quantities of the virus may prolong considerably the length of the incubation, and that by pushing the dilution beyond a certain limit, which is not very high, inoculation of the virus is without effect (*loc. cit.*, p. 340). Now, in this same communication Pasteur declares that he judges the virulence of a virus by the relative shortness of its incubation. So he stands as asserting that a virus used in very small quantity is relatively weaker (as manifested by a lengthened period of incubation), while in the same breath he demonstrates that it is relatively stronger, since it produces more easily the most furious forms of rabies! In this connection we must not overlook the fact that these contradictions have been followed in his last communication on the subject by the astounding assertion of Pasteur that in his preventive inoculations in human beings the attenuation consists not in a reduction of the virulence (the key-stone of the former theories), but in a reduction in the *quantity* of the virus employed.

Again Pasteur here mentions an experiment in which a rabbit after inoculation by trephining had paralysis (*rabic*, he calls it) thirteen days later, and then recovered entirely; but forty-three days afterward the paralysis returned and the animal died in three days. The same, he says, he has also seen in dogs.

Here we note three discrepancies: 1, That inoculation by trephining did not produce the characteristic form of rabies *promptly and surely*, as Pasteur has so often said it will; 2, that it did not produce *furious* rabies at all! and, 3, that the rabies "recovered" and recurred—a thing which never happens in natural rabies.

It was at this time that Pasteur advanced the ingenious theory that inoculation of the hydrophobic virus in different animals (in series) produced a fixed degree of virulence, differing with the species of animals used, and declared that he had found "the practical way to obtain dogs refractory to rabies, in numbers as large as one could wish." He couples this statement with the reasonable assertion that to do this solves the question of the prevention of rabies in dogs and in man. But if this was true in February, 1884, how can we account for the fact that in the two years which have since elapsed not a single dog has been rendered refractory to rabies outside of Pasteur's laboratory?

Pasteur made his sixth communication in his own name and in those of MM. Chamberland and Roux, to the Academy of Medicine, May 20, 1884. It was entitled "Sur la rage" (*Bull. de l'Acad. de Méd.*, 1884, pp. 661–664). In this he announced that he believed he

could "surely bring about a refractory state in (human ?) subjects before the mortal disease breaks out, in consequence of a bite (*loc. cit.*, p. 663)." To a reporter of the *Figaro* he said at this time, "anybody bitten by a mad dog has only to present himself at the laboratory of the École Normale, and by inoculation I will make him completely insusceptible to the effects of hydrophobia, even if bitten subsequently by any number of mad dogs." And, again, "Whoever gets bitten by a mad dog has only to submit to my three little inoculations, and he need not have the slightest fear of hydrophobia." If we pass by the boastfulness of these statements and confine ourselves to a study of the ground upon which they rest, we find that it can be resolved to this: Pasteur claims that when he "extracts" his virus from a mad dog, and inoculates it by trephining upon a monkey, and then from monkey to monkey, it diminishes in intensity. Virus obtained by similar successive inoculations in rabbits increases in intensity. He obtains his attenuated virus, then, by inoculating a series of monkeys (and it is a lucky coincidence, since monkeys are scarce, that it requires only a few monkeys to get what he wants); after which he can grade it up to any point he chooses by transferring it to the rabbit, in series. Thus, by working first backward and then forward, he comes by an attenuated virus, with the weakest power of which he inoculates at the same time a dog and a rabbit; the second inoculation of the dog and a new one in a third rabbit is made from rabbit No. 2; a third inoculation of the dog is made from rabbit No. 3.

"By this time" (*ensuite*), Pasteur claims, "the dog is entirely refractory to rabies, either by intravenous inoculation or by trephining with the virus of dogs with ordinary hydrophobia" (*loc. cit.*, p. 662). In trying to understand this, we ask in vain how he extracts his virus? from what part of the animal he gets it? how he judges that his virus is getting stronger? since he had before asserted (p. 343) that it required a *series* of transmissions to fix the virulence of inoculated virus, and that before reaching this "fixed" point it "*varies ceaselessly.*" This certainly would imply more than three experiments before he could assume any trustworthy diminution or increase in intensity. I have figured it out that if he started with a rabbit dying after an incubation of ten days (the very shortest limit supposable), one experiment would require thirty-two days, four rabbits, and a dog. If his monkeys be supposed to enter into his practice, as well as into his theory, this limit would rise to not less (for three, we will say) than about three months in all, assuming that the weakening of the virus is judged in monkeys also by lengthening of the period of incubation. How many such experiments can we imagine that Pasteur has ever practised. I say "imagine," for he has nowhere given any hint in regard to it.

Once more, this communication contains the following sentence: "By inoculations of the *blood* of rabid animals, in determined conditions, I have succeeded in simplifying considerably the operations of vaccination, and in securing for dogs the most decided refractory state" (*loc. cit.*, p. 663). Here I call your attention to the appearance of blood upon the scene, and the fact that it simplifies matters so much; whereas, we have seen that Pasteur at first denied the inoculability of the blood, and we shall see that, without giving any reason whatever, he soon switches off to the spinal cord, and we hear of this "simplifying" blood no more.

Pasteur's seventh and last communication on this subject is boldly entitled "Méthode pour prévenir la rage après morsure" (*Bull. de l'Acad. de Méd.*, October 27, 1885, pp. 1431–39). In this, after a complacent announcement of the value of his earlier discoveries, he confesses that his previous method would only render refractory to rabies fifteen or sixteen out of twenty dogs. To ascertain the fact of refractoriness requires not less than three or four months, he says, which restricts very much the application of the method—and, I may add, indicates how few experiments he could have carried out to their conclusions.

He had, therefore, attempted to discover a method which he could "dare to call *perfect.*" "After experiments, so to speak, innumerable, I have," he says, "discovered a preventive method, which is practical and prompt, the successful applications of which to dogs are already numerous enough and sure enough for me to have confidence in its general applicability to all animals and to man himself" (*loc. cit.*, p. 1432).

This method may be summarized as follows: An attenuated virus is obtained by inoculating a rabbit, by trephining, with "rabic spinal cord" of a dog dying of ordinary rabies (*rage des rues*), and then a second rabbit with the spinal cord of the first, and so on in series. After a *very long* series it is found that a "virus" is obtained which kills rabbits in seven days. When this point is reached pieces of the spinal cord of one of the victims are removed "with precautions of purity as great as it is possible to secure," and suspended in small flasks in which the air is kept dry by a piece of caustic potash. With each day that it is kept such a piece of spinal cord becomes less virulent.

The treatment consists in taking a small piece of one of these cords and "dissolving" (*délayer*) it in sterilized veal-broth, and injecting a Pravaz syringeful under the skin of the dog. The age of the piece of cord used must be such that it does not endanger the life of the subject of the experiment. How to ascertain the proper age Pasteur says he knows from experience; but unfortunately he forgets to say how any one else may decide the matter (*loc. cit.*, p. 1433). The effect of this treatment Pasteur, when he made his report, had tried on one human being, the now famous Joseph Meister, nine years old, bitten July 4th by a dog supposed to be mad. His bites were numerous. The principal ones had been cauterized the same day with carbolic acid. At an autopsy the dog's stomach was found to contain hay, straw, and bits of wood; and on this fact alone the diagnosis of rabies in the dog rests to this day. Pasteur called Dr. Vulpian and Dr. Grancher to see the boy, and they said he was almost inevitably exposed to contract hydrophobia, "*on account of the severity and the number of his bites.*"

"The death of this child appearing inevitable," Pasteur then decided, "not without keen and cruel solicitude," to try his new method on him. He inoculated the boy with a half syringeful of spinal cord (he says, meaning no doubt diluted or *délayé*) fifteen days old. He made in all twelve hypodermic injections in ten days, each day using a fresher cord, and then sent the boy home cured, having "escaped not only the hydrophobia which his bites might have developed, but that with which I had inoculated him, to test the immunity due to the treatment, a hydrophobia more virulent than that of street dogs" (*loc. cit.*, p. 1436).

In commenting upon this communication there are two sets of objections to be raised. One relates to the case of the boy Joseph Meister, which has attracted such attention the whole world over. The other relates to the general statements made, regarded from a scientific standpoint.

In regard to the case of the boy, it may be briefly stated: 1st, Because there is no proof that the dog that bit him was mad (everybody ought to know that the contents of a dog's stomach are of no value as evidence of rabies), and because the boy's wounds had been cauterized, there is no reason to assume that he was in danger of having hydrophobia; and, 2d, if he was, it is by far too soon to say he is free from the danger.

When we come to compare the assertions in this communication with the evidence in support of them, we do not wonder that the prudent Jules Guérin begged the unwilling President to let him utter a word of protest before this announcement should go out to the world with the sanction of the Academie de Médecine. As usual, Pasteur, in this communication, speaks of his last ex-

periments as "always" successful (*loc. cit.*, p. 1432). Again, his experiments have been "innumerable, so to speak." Unfortunately, here as elsewhere (with one exception), the actual number is not named, and his vague statement will bear analyzing. The conclusions at which he has arrived could only properly rest on a number of *uninterrupted series* of experiments, each complete and successful from beginning to end. Now, I have taken the trouble to figure out what a single series would involve, and I find it means no interruption and no failure in experiments requiring one hundred and thirty or one hundred and forty rabbits, and a period of from about two and a half to nearly three years! An interruption anywhere would break up a whole series. Now—supposing no interruption had occurred—how many such series could Pasteur have been carrying on during the three years since, he says (*loc. cit.*, p. 1432), he began them? Again, what seems to me the most fatal objection to the idea that Pasteur's experiments could possibly have been trustworthy throughout these immense series is the fact that, by his own admission, *a full half* of the spinal cords, used in the crucial experiment on Joseph Meister, which gave him such "cruel inquietudes"—as well it might—*proved to have no virus* when tested on rabbits! Out of eleven, he says, five were without virus, five were virulent; and of one, singularly enough, he says nothing (*loc. cit.*, p. 1436). If this could happen in the only detailed experiment which Pasteur has ever recorded, and when everything seemed to depend upon the infallibility which Pasteur had so often claimed, what are we to think of the experiments done in the secrecy of his laboratory, of which no record has ever been given, and of which not a single witness has ever spoken except Pasteur?

Another matter to be remarked just here is that until now Pasteur had given no hint that the virus of hydrophobia could be attenuated so simply as by desiccating the spinal cord. And yet, if his own statements are true, he must have been far advanced in his experience with this method at the very time when he was startling the world with his backward and forward modifications of the virus in monkeys and rabbits, and presenting this as the way to obtain the virus for what he called his "three little inoculations." If we take the trouble to place side by side Pasteur's statements at different times, we see that they are so inconsistent that the cordial acceptance of almost any one of them seems to demand that the preceding ones should be banished from our memory. At first it was in the brain that the virus was to be obtained in perfect purity; then trephining and intradural inoculation was the sovereign method; then intravenous inoculations were said to simplify the matter; then blood was a good virus; then smaller quantities produced fiercer rabies; then inoculations in series modified the virus after many variations; then a few monkeys and rabbits did the work; then rabbits alone sufficed, while the virus was weakened by drying the cord. And, to crown all, forgetting the traditions of his own work in regard to charbon and chicken cholera, Pasteur says that the protective character of his virus depends upon a reduction in quantity and not in the virulence of the virus (*loc. cit.*, p. 1437).

What! And when we catch our breath, we cannot but recall what has gone before, and say: If the hypodermic injection of reduced quantities of virus was the means Pasteur found would most readily produce the most furious forms of rabies, in February, 1884, when he must have been half-way through the series of experiments upon which the present communication rests, how could the remaining half have sufficed to show that the same way of proceeding would exert a kind and protective influence on the same animals and on men?

But I must close my comments on this communication with the latest of Pasteur's theories. He actually intimates that the virus of hydrophobia "may be formed of two distinct substances, and that by the side of one which is animate and capable of germinating in the nervous system, there may be another, inanimate, having the power, when in proper proportions, to arrest the development of the former" (*loc. cit.*, 1438).

Since M. Pasteur made his last communication to the Académie de Médecine and to the Académie des Sciences, the enterprising *New York Herald* has given much space to discussing his method and its application. We have all heard of the four children sent from Newark to Paris after being bitten by a dog of which there is not the remotest evidence that it was mad, and of their return to America in apparently as good a state of health as is still enjoyed by the remaining two, who were bitten at the same time by the same dog, and who have never stirred from home. Three other Americans have gone over, viz., a man named Kaufmann, another by the name of Sattler, and a boy named Edward Bucklin. In regard to these patients there is equally little evidence that they have been exposed to the bite of a rabid dog. Indeed, in the case of one of them, it is denied that he was bitten at all. Pasteur is said to have refused to practise on him, and again he is said to have done so. All these seem to have maintained their health in spite of their bites, their fears, their long journey, and their inoculations with Pasteur's weak and strong viruses. One of M. Pasteur's patients, a girl, aged six, died of rabies while under treatment by him. This mishap Pasteur explained by saying she had come to him thirty-six days after being bitten, and that the virus in her system had made too great progress to be stopped. Its rapid action he explained on account of her youth—an assertion which is not borne out by facts—and because she had been bitten on the head, *i.e.*, near to the brain. This latter explanation is in accord with one of Pasteur's theories borrowed from Davaine; but it is also opposed to facts with which he should have been familiar; for, as lately as April 8, 1884, Dr. Dujardin-Beaumetz added, to what was clear enough before to any one who had carefully studied the subject, the confirmation of a report to the Academy of Medicine, of which M. Pasteur is a member, on the cases occurring in the Department of the Seine, in the three years 1881, 1882, and 1883 (thirty-four cases in all), which showed that there was no relation between the point of inoculation and the period of incubation.

On December 8th Pasteur said: "I am confident my treatment will be successful, if commenced *at any time before actual hydrophobia sets in*, even if a year or more elapses between the bite and the commencement of treatment." This was on the very day, I believe, on which the little girl died, and suggested to him that thirty-six days was a long time to wait, while on January 1st of this year he says that his treatment is efficacious *even* fifteen days after a bite!

The very last utterance of Pasteur on this subject is contained in the statement prepared for the *New York Herald*, under his direction, by his assistant, M. E. Wasserzug, on January 1st of this year. This embodies a good account of his last method, in which it is noticeable that while he specifies that he uses half a Pravaz syringeful of his mixture of rabic medulla and sterilized veal-broth for a child (as compared with three-quarters of a syringeful used for adults), he omits entirely—as he has *invariably* omitted—to say how much of the veal-broth is used to mix with a given quantity of so-called rabic spinal cord. This quite material omission is accompanied by two opposite statements: one, that his method is "very simple and very practicable;" and the other, that "outside of M. Pasteur, and of his laboratory, there does not exist a single person in the world capable of undertaking the treatment with certainty of success (*sûrement*)."

This must prove a disappointing *dictum* to those well-meaning men in New York who so hopefully incorporated a *Pasteur Institute* on January 2d; although it cannot be considered too harsh a judgment of the men in St. Louis, who, on December 31, 1885, "perfected

arrangements for the treatment of hydrophobia after the method followed by M. Pasteur," announcing that "in three weeks, at the outside, patients may be treated."

It is very true, as Pasteur declared, on January 4th, to an American in Paris, that in this matter our countrymen "go too fast"—although it seems a pity that he should have applied this expression to the men of New York who so trustfully relied upon his help; while he cannot have known of those in St. Louis who proposed to imitate him by accomplishing in about two weeks what he says requires two years. For the credit of our country let us hope that Pasteur will never hear of some of the New York men, whose names appear in the *Herald*, who proposed to cultivate the "bacteria" of rabies in "glycerine and agar-agar jelly." If he does, he may wonder that our scientific men do not know that he has never found a bacterium in this disease, or that he has never said a word about cultivating his virus in glycerine or agar-agar jelly.

And now when we look back over the whole of M. Pasteur's work in connection with the subject of hydrophobia, how shall we judge it? The final impression is —to say the least—disappointing. In spite of the distinctness of his assertion and belief that he has solved the problem of the cure of hydrophobia, or of its prevention at any time before its outbreak, when we try to follow the steps by which he has reached this conclusion we find ourselves in bewilderment. We seem to be in a maze, travelling blindfolded, cheered here and there by his assurance that all will be well. At length he seems to say, "Look about you, we are safe!" But when we look about, the safety does not appear. The proofs of it are still nothing but his bare assertions. When we examine these we find they are in part contradictory of each other, while in part they contradict facts of which he does not seem to be aware. When we seek for evidence that he is familiar with the clinical manifestations of what is called hydrophobia, or with its history in past ages, we cannot find it. It does not appear anywhere that he has ever seen a case of this sort or ever studied the descriptions which others have given of it. The same is true in regard to the work of others who have studied hydrophobia experimentally. He seems to be ignorant of, or he wilfully ignores, the labors of his own countrymen, never mentioning one as if he had contributed anything of value to our knowledge of the subject, and being doubtless utterly unaware that any one outside of France has brought patience, perseverance, and skill to bear on the intricate problem.

The very outset of his work in the beginning of 1881 is marked by a positive announcement of a new microbe and a new disease, and an angry repudiation of the suggestion of Colin that control investigations and experiments would show that neither microbe nor disease was new.

This announcement, however, was soon shown to be erroneous in every part of it. He next adopts the ingenious (but mistaken) notion of Davaine, that the nervous system is the channel, and its centre the goal, of the virus of hydrophobia; for which appropriation of his ideas Davaine soon appeared in the lists against Pasteur and joined the number of those who have questioned his honesty as well as his ability.

A year and a half later, December 12, 1882, Pasteur claims to have discovered that the virus of hydrophobia has its principal seat in the brain, and that it there can be gathered in perfect purity and inoculated with absolute certainty, its effects being "prompt and sure." We have not time to discuss the theoretical objections to this assertion, which are very many; it is enough to point out that although Pasteur has repeated it many times, it has never been confirmed outside of his laboratory, and it stands opposed to the experiments of a much more candid experimenter, Galtier, of Lyons, and that it is not true of what happens even in Pasteur's own laboratory, for some of his animals recovered spontaneously (*Bull. de l'Acad. de Méd.*, 1883, p. 1151).

He next announces the finding of the virus in the spinal cord, often in all parts of it. The evidence of this, as of the preceding assertion, rests upon Pasteur's opinion of what may be called rabies. This we have already seen to be elastic enough to cover almost any result of his experiments, and entirely too elastic to be trustworthy.

Fourteen months after this, Pasteur announced a new doctrine, viz., that when what he calls hydrophobic virus is introduced into the circulation it becomes "fixed" and multiplies, at first in the spinal cord, and that one part of the cord might contain the virus when the rest did not. This is, on its face, simply absurd; but it illustrates the boldness of Pasteur in filling up with an assertion a gap in his demonstrations. This very boldness has misled some who have followed with incautious and uncritical haste the rapid succession of brilliant discoveries announced by Pasteur. For example, when he passes smoothly over an admission that he has never discovered a microbe in his virus, that he is only "tempted to believe," in one of infinite smallness from the detection of certain *minute* granules, by which he claims to be able to distinguish a rabid brain from a healthy one, who pauses to reflect that, on the one hand, he has never demonstrated his skill in this mode of diagnosis; and, on the other hand, that such granules as he speaks of were described before he had thought of them, and are not peculiar to the brains of rabid animals at all?

Again, when Pasteur casually admits that he has never been able to cultivate or to isolate what he calls the virus of hydrophobia outside of the body, who calls attention to the relation of this admission to the fundamental principles of his own work in regard to anthrax and fowl-cholera? Again, who has lifted up a voice against the contradiction of these fundamental principles in Pasteur's assertion that he could produce the more grave and furious forms of hydrophobia on the sole condition of using a weaker virus, and less of it? And is it not new to-day, to ask how, if this be true, it can also be true that his so-called protective virus owes its protective character to a reduction in the *quantity* and not in the *quality* of the virulent material? or how this last statement can be believed at all?

The next theory announced by Pasteur was that inoculation of animals in series produced a fixed degree of virulence for each species; and for want of opportunity to experiment on man that monkeys could be considered a suitable substitute. This latter idea shows how Pasteur has been misled by the supposition that similarity of physical structure indicates a similarity in physiological nature—an error which has been admirably exposed (*apropos* of another matter) by M. Béchamp (*Bull. de l'Acad. de Méd.*, May 8, 1883).

In May, 1874, came Pasteur's announcement that by weakening his virus by transmission through monkeys, and by strengthening it by transmission through rabbits, he had obtained a virus which would prove protective in dogs, and the application of which would eradicate hydrophobia from the world. In regard to this claim I content myself with a single remark, viz., that in the two years which have elapsed since Pasteur made it, not a single dog has been made refractory to rabies outside of his laboratory; and that in his laboratory he has only succeeded in rendering "refractory," as he calls it, fifteen or sixteen out of twenty dogs!

The next and last announcement of Pasteur, made last October, was that he had devised a method to prevent the outbreak of hydrophobia after the bite of a mad dog. In this method we find him, without any explanation, dropping entirely the recent theory about monkeys as a part of the machinery for manipulating his virus, and passing by what he had declared to be a simpler mode of operating, viz., by intravenous inoculation, to take up hypodermic injection as the method of inoculating, pieces of spinal cord, rubbed up in an unstated quantity of veal-

broth as a virus, desiccation as a means of attenuation, with the astounding explanation that the protective character of his virus was due to a reduction in quantity and not in quality! It seems strange that Pasteur should not have noticed the mutual contradictions of different parts of this announcement; but it is still stranger that he should have failed to see the destructive inference to be drawn from the facts to which I have already alluded—that in his crucial test (in the case of the boy Meister) one-half of the inoculation afterward proved to contain no virus whatever!

Finally, we have Pasteur's positive announcement that his method would prove protective at any time before the outbreak of hydrophobia, even if one or two years had elapsed since the bite, which he stuck to until a case dying under his hands led him to reduce this long period at one sweep to thirty-five days, which was soon after cut down to about fifteen. How soon the short space of fifteen days may be reduced to fifteen minutes we may tremble to contemplate, in view of the rapid rate of reduction which has prevailed thus far.

One other point must not be overlooked in judging Pasteur's theories from a scientific standpoint, and that is, that he has utterly abandoned the only natural virus of hydrophobia, the only one which can be asserted to communicate the disorder from one animal to another—the saliva—and has used an artificial irritant, which probably has never produced rabies at all, but only a peculiar form of septic or simple inflammatory disease, of the significance of which his lack of medical education and experience make him unfit to judge, and which he has quite arbitrarily labelled hydrophobia!

The results of the application of Pasteur's method may be summed up as follows: One death under his hands, with a lame explanation; over a hundred persons to testify that his inoculations probably do no immediate harm; an almost equal number to illustrate the well-known advantage of having one's fears allayed—in all, no more than is credited to a host of nostrums. Besides which, the excitement it has aroused has brought about a senseless alarm in regard to dogs, and the killing of innumerable innocent and unfortunate animals to bear witness to the sharpening of men's fears and the dulling of their judgment.

In conclusion, then, I venture to express my opinion that Pasteur's so-called method of treating hydrophobia before the outbreak *does* appear to be founded upon untrustworthy experiments and unsound reasoning, and ought to be rejected and condemned, in the interests of humanity as well as of science.

But while I thus characterize this last work of M. Pasteur, let me not be misunderstood. Here, as in other theories and practices which he has presented to the world, there is much to criticise. Pasteur's arrogance, impatience of correction, ignorance or disparagement of what others have done; his secret methods, his hasty assumptions, his illogical conclusions—have made him many scientific and personal enemies. But, after all, Pasteur is the man who placed on a new and apparently secure basis our knowledge of the nature of ferments; who disproved the theory of spontaneous generation; who laid the foundation upon which rests the whole system of antiseptic surgery, for the establishment of which the name of Lister will be justly immortal. Such a man is Pasteur; and, whatever of error may seem to mar some of his best endeavors, and however the future may adjudicate their claims, he seems to me to deserve all the honor he has received for his unwearied labors, and his magnificent achievements in the cause of science.

His very achievements in the right direction, however, make any error on his part all the more dangerous to the cause of truth, and make it all the more the duty of thinking men to sift the evidence upon which he rests his extravagant claim of having discovered a means of preventing the outbreak of hydrophobia.

THE INTRA-CEREBRAL TRACTS.

Their Physiology, and Its Bearing Upon the Diagnosis of Lesions of the Centrum Semi-ovale.

By M. ALLEN STARR, M.D., PH.D.,

PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM, NEW YORK POLYCLINIC.

The diagnosis of lesions involving the mass of white substance lying beneath the cortex of the brain and above the level of the basal ganglia is involved in obscurity. . Such authorities as Nothnagel,[1] Charcot,[2] and Strümpell[3] admit that few rules for guidance can be given, and at present there are no definite symptoms assigned to diseases of the centrum semi-ovale.

The subject of lesions of this part of the brain has an immediate practical bearing. In the journals of the past year are recorded several cases of operations upon the brain for the evacuation of cerebral abscesses, and the excision of tumors. This is, doubtless, but a beginning of a brilliant advance in the department of cerebral surgery soon to be made.

And the surgeon is here dependent upon the neurologist; for he will not cut down until he is told where to cut down. Now we know that tumors and abscesses—the legitimate field for operation—lie chiefly in the centrum semi-ovale. Hence the diagnosis of lesions in this part is to-day one of the most pressing and important questions in the field of neurology.

The natural manner of approaching a subject of this nature is to follow the inductive method, and, by a collection of cases in which an autopsy has demonstrated the existence of a lesion, to collate the common symptoms and thus arrive at the diagnostic conclusions. But while this method does afford a certain number of facts of importance, it is, as we shall see, by no means as satisfactory as in the case of cortical lesions, in the investigation of which it has given such brilliant results. For lesions of the centrum ovale are not very common, and, therefore, are not often suspected during life. An examination directed toward the symptoms which such lesions might cause is therefore frequently omitted, and hence facts are wanting in the recorded histories which would serve to establish a symptomatology of these diseases. There are many symptoms in every case which must be sought for by the examiner, as they are of a character to escape the notice of the patient. Disturbances of the temperature sense, of vasomotor activity, of the power of locating the position of certain muscles, or of the exact limitation of the visual field, are all instances in point. It is evident, therefore, that some of the symptoms of lesions in the centrum ovale may have escaped notice because they were not properly investigated. And it follows that we must ascertain the probable nature of those symptoms from other data than those furnished by the recorded cases.

It seems to have been a constant fact in the history of progress in clinical medicine that, just in proportion to our knowledge of the anatomy and physiology of a part, does our knowledge of the symptomatology of its diseases advance. To bring symptoms into connection with lesions is the aim of scientific investigation, and this has been done chiefly along the lines of anatomy and physiology.

Hence, in investigating lesions of the centrum ovale, we may turn from pathology to anatomy for the information needed to establish the symptoms of such forms of disease.

The anatomy of the centrum ovale can be studied to the best advantage upon torn brains, which have been properly hardened in alcohol. A dissection made in this manner with care enables one to establish the fact that this part of the brain is made up of fibres only, and to distinguish easily three sets of fibres passing through it.

1 Nothnagel: Topische Diagnostik der Gehirnkrankheiten. 1879.
2 Charcot: Revue de Médecine, 1881. Localisations cérébrales.
3 Strümpell: Lehrbuch der Nervenkrankheiten. 1884.

These three sets have been named the *projection*, *commissural*, and *association* systems of fibres.

The *projection* system includes those fibres which connect a definite area of the cortex with parts of the nervous system lying below it. It therefore follows that but one termination of a projection fibre is found in the cortex, and hence the fibre, in passing through the centrum ovale, is either on its way to, or on its way from, some nervous mechanism in the basal ganglia, brain axis, or spinal cord. Indirectly, through the medium of such mechanisms the external world is projected upon the brain and reaches consciousness, and voluntary impulses originating in the brain are sent to and affect the external world. A dissection of the centrum ovale, prepared

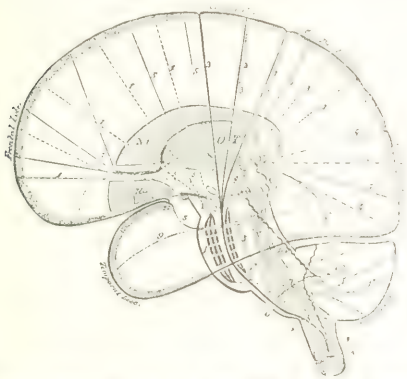

Fig. 1.—[illegible] (Modified after [illegible] cerebellum; 2, motor tract from central convolutions through capsule, crus, pons and medulla; [illegible] lobe through [illegible] way to the [illegible] capital lobe to optic thalamus; 5, optic thalamus radiation to all the lobes; 6, auditory tract from temporal lobe to optic thalamus; O. T., optic thalamus; N. L., lenticular nucleus; N. C., caudate nucleus; R. N., red nucleus of tegmentum; O, olive; C. D., corpus dentatum; 7, tract between O. and C. D.; Q. Corp. quadrigem

so as to show the projection system, demonstrates the existence of fibres from the entire cortex passing downward and gathering together within the hemisphere at the upper level of the basal ganglia, and either ending in the optic thalamus, or going on between these ganglia to the brain axis and spinal cord.

The majority of these fibres end in the optic thalamus, which is thus connected with all parts of the cortex of the brain (Fig. 1, 5). Of the function of these we know very little. Two large bundles, however, are separable from the mass. One of these passes inward and forward, from the occipital lobe and joins the pulvinar of the thalamus and the external geniculate body (Fig. 1, 4). This is now known as the visual tract, and conveys impulses received from one-half of each retina by the optic thalamus to the like-named occipital lobe, as has been proven by recent articles on hemianopsia.[1] A second bundle passes from the temporal lobe inward to the thalamus and internal geniculate body, lying just beneath the first at its point of entrance into the thalamus (Fig. 1, 9). This conveys impulses of sound from both ears to each temporal lobe, as the investigations of Von Monakow, by the atrophy method, have shown.[2] These are the only bundles of the thalamic radiations whose function is determined.

Some of the projection fibres pass on without communicating with the basal ganglia, and of these we know three distinct bundles.

The first is collected from the three convolutions of the frontal lobe, and passing between the caudate and lenticular nuclei in the anterior division of the internal capsule, descends in it to the base of the brain, and issuing in the inner third of the foot of the crus cerebri, passes down to the pons, where it terminates in nuclei lying in the ventral half (Fig. 1, 1). The nuclei thus reached by these fibres are also joined by other fibres from both hemispheres of the cerebellum, which enter the pons at its lateral surfaces in the middle peduncles. Thus it is evident that a connection exists between each frontal lobe and both cerebellar hemispheres, the crossed connection being greater than the direct one. In Flechsig's case of deficient cerebellum, the pons nuclei and the fibres to them from the frontal lobe were found.[1] In my case of deficient cerebrum the pons nuclei and the fibres to them from the cerebellum were found.[2] Therefore each half of this tract, if it is a continuous tract, may develop independently of the other.

Of the function of this tract we know nothing, and of the functions of the frontal lobes and cerebellar hemispheres we know very little. Therefore we cannot as yet connect any symptoms with its destruction.

The second bundle of the projection system, passing out of the base through the middle third of the crus cerebri, comes from the posterior part of the third frontal convolution, the two central convolutions, and from the paracentral lobule. Its fibres collect at the middle portion of the upper surface of the internal capsule, those from the lower parts of the cortex passing straight inward, those from the upper parts curving outward and downward to pass around the side of the lateral ventricle. Thus within the centrum ovale these fibres, if looked at from in front, appear like the sticks of a fan, and like those sticks their relative position is altered in the point of junction, where those passing inward from the lowest part of the cortex lie in front of those which pass downward from its upper part (Fig. 1, 2). Thus in the capsule the order from before backward is, *first*, the fibres conveying speech impulses to the pons and medulla; *second*, the fibres conveying facial motor impulses to the pons; *third*, the fibres destined to the arm centres of the cord; *fourth*, the fibres transmitting impulses to the leg centres in the cord. The impulses to the muscles of the trunk may lie behind or in front of those to the leg, as this is not yet determined. The fact that they are only implicated in severe cases of hemiplegia, and not in all cases, would indicate that they occupy the place back of the tract to the leg.

This is the great motor tract, whose course through the anterior half of the posterior division of the capsule is well known, and which can be traced through the middle third of each crus, through the pons, and thence by way of the pyramids of the medulla to the crossed pyramidal and anterior median columns of the spinal cord. It is evident, however, that the concentration of this tract is much greater in the capsule than in the centrum ovale, where the individual fibres are scattered among the other systems and occupy but a small area from before backward. Lesions beneath the third frontal convolution of the left side produce motor aphasia. Lesions beneath the central convolutions in the centrum ovale produce paralysis, which will vary according to the position of the lesion. The nearer the lesion lies to the cortex the more will the symptoms resemble those of cortical disease, monoplegia being the rule. The nearer the lesion to the point of junction at the capsule the more will the symptoms resemble those of capsule lesion, hemiplegia being the rule. There are numerous cases recorded in support of this statement.[3]

The third set of fibres of the projection system includes those which lie just posterior to the motor tract, and which pass inward from the parietal convolutions (Fig. 1, 3). These take a similar course to those of the motor tract, and fill up to a considerable extent the space between it

and the radiation of the visual tract, toward the occipital lobe. They are mingled with fibres which pass to the optic thalamus, but are separable from them, as Edinger has shown in fœtal brains,[1] and may be traced down through the capsule to the tegmentum of the crus, where they divide into a portion going to the lemniscus, and a portion going to the formatio reticularis. This set of fibres conveys the sensations of touch, pain, temperature, and muscular sense,[2] and lesions in its course will cause disturbance of these sensations. Like lesions in the motor tract, the rule obtains that the nearer the cortex the more likely is the lesion to cause an affection of a single limb, while the nearer the capsule the more likely is the symptom produced to be hemianæsthesia.

Looking, then, at the dissection of the projection system of fibres, it is evident that a lesion which lies in the centrum ovale at any point posterior to the præcentral fissure of the frontal lobe, may produce recognizable symptoms, for it must affect either the motor, or the sensory, or the visual, or the auditory tracts, or individual fibres of those tracts. In the latter case it will be necessary to examine carefully for symptoms, as they may escape a superficial notice.

The second system of fibres in the centrum ovale is the *commissural* system. This joins corresponding areas of the two hemispheres with one another. The commissural fibres between the frontal, parietal, and occipital lobes of the two sides pass in the corpus callosum, the view of Hamilton, of Aberdeen, that these fibres are not commissural being disproved by the researches of Spitzka and Beevor.[3] Those from the temporal lobes pass in the anterior commissure. The function of these fibres is to harmonize the action of the two hemispheres. This may be proven with regard to the fibres which join the central convolutions with each other, and harmonize motor acts. Every one knows that simultaneous movements of like nature can be made with great facility with both upper extremities. An attempt to swing Indian clubs is more difficult if each hand is executing a different motion. So, too, movements which are difficult when attempted with the left hand alone become easy when associated with corresponding movements of the right hand—as, for example, drawing a circle, writing one's name. But the motion, in order to be associated by the commissural fibres, must involve the corresponding muscles on both sides of the body. Hence, if the right hand moves to the right the left must move to the left to a similar degree in order to bring into play the aid of commissural association. Hence, such writing with the left hand will be backward, and can only be read by the aid of a mirror. Now, it is a very simple thing to test this power of symmetrical movement in persons, but I venture to state that it is very rarely done; so that no clue is usually obtained as to the condition of conducting power in the commissural fibres in cases of brain disease. It is the commissural fibres joining the motor convolutions only which can be thus tested. Failure to perform easily corresponding bilateral motions in face, hands or feet would indicate some obstruction to conduction in them. With regard to the fibres lying in the anterior part of the corpus callosum and joining the frontal lobes, little can be said except that in numerous cases of idiocy these fibres have been wanting. The cases of McBride (*Amer. Jour. Neurol.*, May, 1884) and of Erb (*Virchow's Arch.*, Bd. 98) of lesion of the corpus callosum presented no peculiar local symptoms. Nor have we any power of testing the integrity of commissural fibres lying posterior to the motor tract, though a theoretical statement will not be objected to, that those between the occipital lobes are very important, inasmuch as each occipital lobe receives impulses from but one-half of each retina. Hence, integ-

rity of both occipital lobes and simultaneous, connected, and harmonious action in both is necessary to the *perfect* perception of the *whole* of any object when the eyes are fixed upon one point of that object. The function of the anterior commissure is wholly unknown. Theoretically, a lesion of the commissural fibres should produce a lack of harmony in the simultaneous action of the two hemispheres, and if the lesion in the centrum ovale lay opposite to the two central convolutions this could be detected by appropriate tests.

The third system of fibres in the centrum ovale is the *association* system, and this requires a careful study.

It can be shown by careful dissection that each convolution is joined to the two adjacent convolutions by fibres which pass around the separating fissures. Also, that bundles of fibres exist which pass from each convolution to the convolution next but one, and so on. Hence, it may be stated that each convolution has a possible connection with every other. Besides this association of convolutions by small bundles of fibres, it is possible to find a distinct set of association tracts which pass between more or less distant regions. One such tract passes from the frontal lobe, collecting its bundles from all three convolutions, backward to the occipital lobe. Another tract joins the occipital with the anterior part of

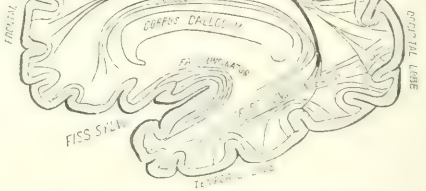

FIG. 2.—Association Fibres in the Centrum Ovale. (Modified after Edinger.) Fasc. arcuatus = fronto-occipital and fronto-temporal tracts; Fasc. uncinatus = temporo-frontal tract; Fasc. longit. inferior = occipito-temporal tract.

the temporal lobe. Another passes from the upper two temporal convolutions forward to the third frontal convolution, passing beneath the island of Reil. And a tract from the parietal to the posterior temporal area may also be found.

What can be the function of these association fibres? Without going very deeply into the subject of psychology, it may be suggested that they form the physical basis for the association of concrete memories.

Our concrete memories are reproductions of former rensations. But if the sensations are received in various saeas of the brain, as we must admit from the facts already stated regarding the function of the projection fibres, it is evident that the reproduced sensation which depends on the revival of the original sensation will occur in the same part of the brain in which the original sensation was received. A sight memory is located in a different part of the brain from a sound, or touch, or motor, or speech, or writing memory. And this fact will be readily admitted by those who have seen cases in which a single set of memories have been lost while others remain. The symptoms of word deafness, word blindness, aphasia, agraphia, alexia, are all symptoms dependent upon loss of a definite set of memories. And they are usually due to definite lesions of the cortex in different areas, which we are now able, by the aid of numerous autopsies, to specify. But no concrete memory can be said to exist without associations. The sight of a dog leads us at once to think of the form and appearance of other dogs, of animals resembling dogs, and of quadrupeds in general. Thus the impulse received in a memory area excites other memories of a *like* quality.

[1] [illegible]

[2] [illegible] cit. (Forty-two Cases with Autopsies).

[3] [illegible]; Beevor: Brain, October, 1885; [illegible] Amer. Jour. Neurol., August, [illegible].

Further, the sight of a dog might easily lead us to think of his bark, or, if we had once felt it, of his bite; and that because originally the simultaneous occurrence of the sight and sound of the animal had associated the two memories forever. Thus an impulse received in a memory area may excite other memories of an *unlike* quality. In fact, any one of our concrete ideas may be said to be made up of a number of associated memory pictures, all of them united into a definite whole. My idea of an orange is made up of my memory of the appearance of the orange, its color and form, of the memory of its odor and taste, of the peculiar feeling of its surface, of the sound which I know as its name, of the motion necessary in my throat and lips to pronounce the word which designates it, and of the movements necessary to write the word orange. And further, each one of these memories is joined not only to the next, but also to all the others, for if you show me an orange and ask me to say or to think or to write its name, I can do either at your will, and need not say it before I write it, or taste it before I can call to mind its odor.

These facts of concrete memory gained by introspection show how intimate is the connection between our various kinds of memories, and demonstrate *à priori* the need of just such sets of association fibres in the brain as we have found by anatomical dissection. It may be stated, therefore, that the association fibres of the centrum ovale have as a function the harmonizing of the activities of the various cortical areas. They are necessary to the union of different memories in a whole, to the formation of a concrete idea. I do not now allude to abstract ideas, or to processes of reasoning. I have spoken only of concrete ideas, for it is only regarding these that our investigation of cases of localized brain disease will allow us to speak. But if these association fibres pass through the centrum ovale, it is evident that the integrity of the centrum ovale is necessary to their proper action, and that lesions of the centrum ovale will lead to a separation or failure of association of ideas and memories formerly joined. If the fibre is broken which joins my memory picture of a familiar face with my memory picture of the sound or name associated with that face, I cannot call the person by name on seeing him. If I have lost the power of copying a page that is placed before me and which I can see, it is possibly because I no longer associate the sight of a letter with the motion of my hand necessary to write that letter, an association originally made by practice. If I can understand what is said to me, and can pronounce words distinctly, but talk jargon or replace one word by another, it is because the fibres which join corresponding auditory and motor speech memories are unable to perform their function. A patient whom I saw recently was asked to name the four of spades, a card which I picked up from the table at which he had been playing whist. He said at once five of telephone, and was much put out at his mistake. These are instances of a defective conduction between the occipital and temporal, between the occipital and frontal, between the temporal and frontal areas, and we have already seen that it is just between these very areas that great association tracts extend.

It is evident, therefore, that we have not only a knowledge of the anatomy and physiology of the association fibres of the centrum ovale, but also a set of symptoms referable to their destruction. But here, again, it must be emphasized that careful examination of cases in a proper way is necessary in order to detect a lesion of such fibres. In the case of the fibres associating the auditory with the motor speech areas, the symptoms to be elicited seem very simple. Can the patient talk correctly? Can he repeat at once a word spoken to him? These are questions which any one will ask who examines a case of aphasia. But this is not all. The patient must be further questioned. Can he read understandingly to himself, and tell what he has read? This will test the occipito-temporal tract. Can he read aloud? This will test the occipito-temporo-frontal tract. Can he write what he sees? This will test his occipito-central tract. Can he write what he hears? This will test the temporo-central tract. Can he write what he says, speaking to himself in a whisper? This will test his fronto-central tract. Can he name an odor or a color? Brill has recorded[1] a case of lesion of the cuneus associated with color blindness to green, and he states that the patient had difficulty in naming various colors on account of the presence of a slight degree of amnesic aphasia. This aphasia was most marked in regard to names of colors, not in regard to contours, for he would compare colors to the tints of common objects. The aphasia was limited to the names of those colors which were imperfectly perceived—green and violet. Can the patient write the name of an odor? Can he tell how a surface feels—smooth, or warm, or heavy? Such questions as these will suggest themselves at once to any one who studies the association of ideas subjectively, or who will tear out the association fibres between the various areas of the brain cortex, and, knowing the function of the areas, consider the probable use of their association fibres.

It is evident, therefore, that a lesion of the centrum ovale may give rise to three sets of symptoms, referable to projection, commissural, and association fibres. The important fact at once appears that these symptoms will be inevitably associated in any case of its occurrence. It is upon the fact of such *association* of symptoms that the diagnosis of lesions of the centrum ovale must depend. Monoplegia alone may be caused by cortical or centrum ovale disease. Hemiplegia may be caused by capsular or centrum ovale disease. But if in either case it is the centrum ovale which is diseased, there will be in addition to the paralysis a suspension of action of commissural and association fibres. The commissural fibres being destroyed, simultaneous bilateral symmetrical motions will be suspended. The association fibres being destroyed, certain mental associations will be affected. Take as an example a lesion in the centrum ovale of the occipito-temporal region. Such a lesion will produce hemianopsia because it involves the visual tract of the projection system. It may also produce a peculiar mental condition known as word blindness, in which the patient is no longer able to associate a word or letter seen with its corresponding sound, or with the motion necessary to write it. Charcot has reported a case of this kind, and as I had an opportunity to see and examine the patient under his direction, I may be excused for mentioning it in detail. The man, who was a very intelligent merchant, was suddenly seized with right hemianopsia while playing billiards, and was surprised to find that he saw but one-half of the ball and of the table. Soon after he had occasion to write a letter, and after writing it was surprised to find that he could not read what he had just written. He found, however, that on tracing individual letters with the pen or fingers he became conscious of the letter—a few letters (r, s, t, x, y, z), however, being an exception to this rule. When a book was given him to read, he would trace out the forms of the letters with some rapidity and thus manage to make out the words. If his hands were put behind him and he was asked to read, he would still be observed to put his fingers in motion and to trace the letters in the air. Speech was in no way interfered with, but reading aloud was only accomplished like reading to himself by the aid of muscular sense. Here, then, was an example of a lesion which had separated entirely the tract associating sight with speech, viz., the occipito-temporal tract, but had left intact the tract associating sight with muscular sense, viz., the occipito-central tract.

The first tract, the occipito-temporal, lies side by side with the visual, and its implication in the lesion which caused the hemianopsia is not to be wondered at. The

[1] American Journal of Neurology, February, 1885.

second tract, the occipito-frontal, lies much higher in the centrum ovale and evidently escaped (see Fig. 2). Now, had this patient been an unintelligent laborer, seldom called upon to read or write, such a peculiar symptom might have escaped notice, and although it might have been discovered that he had alexia, the possibility of his being able to read by means of his muscular sense would only have been elicited by proper investigation. This case also illustrates a possible point of differential diagnosis between lesions of the centrum ovale and lesions of the cortex. If the lesion is in the cortex, some one of the cortical functions, *e.g.*, sight or motion, will be suspended together with their memories; while in lesion of the centrum ovale it is only the association of two or more memories which will be impaired. Is it not possible that in cases of word blindness the symptoms are due to such a break of the association tracts when sight and speech are preserved? Certainly, in the numerous cases of lesion found, the centrum ovale just beneath the cortex, at the posterior end of the Sylvian fissure, has been involved as well as this cortical area, and it is just in this portion of the centrum ovale that the occipito-temporal tract lies.[1]

Such a case as I have related you may say is rare. Are we sure of this? Can we say that in the majority of brain cases a thorough examination of the powers of association is made? And does not the anatomy and physiology of the centrum ovale lead us to believe that its lesions might produce just such symptoms or others somewhat similar? Is it not worth while, in all cases of obscure brain disease, to examine *all* the functions of which we have any knowledge, trusting to the future to explain peculiar symptoms which may be thus discovered? There is a psychological deduction which occurs naturally from the study of the case just related. The man could see the letter so as to be able to trace its form, and yet the sight alone conveyed to him no idea. We have already seen in studying the association fibres, that a concrete idea must be considered as a complex collection of memory pictures. Is it not evident from this case that a single one of these pictures isolated from the rest is incapable of awakening a concrete idea? The patient only obtained the idea when he put into action the motor memory, whose connections with sight and sound and speech were all intact. We have spoken only of concrete ideas. If we conceive of abstract ideas as made up of a numerous assemblage of concrete ideas, as they possibly may be, brought into consciousness as a single concept by the aid of the name or word, is it not probable that lesions of the centrum ovale will give rise to a confusion of abstract as well as of concrete ideas? And is it not possible that the symptoms of mental confusion of that peculiar kind which occurs in diseases of the frontal lobes of the brain, may be ascribed to a suspension of action of association and commissural fibres which pass in all directions through the frontal lobes? Many cases are on record of extensive disease of the frontal lobes in which the patients have presented mental symptoms, not those of any form of insanity, but rather of a form of mental hebetude or bewilderment; so that they act rather after the manner of mutilated animals—careless of the wants of nature—regardless of all restrictions of society, morality, and decency—being in a state in which mental inhibition and mental activity were impossible. These symptoms cannot be assigned wholly to disease of the frontal cortex, for in the majority of cases on record the centrum ovale was involved as well, and in not a few it was in the centrum ovale that the lesion was most extensive. These, then, may be found to be symptoms of lesion of the centrum ovale beneath the frontal lobes.

Nothnagel, in his great work, "Topische Diagnostik," has said that there are no diagnostic local symptoms of lesion of the centrum ovale. Such symptoms as headache, vertigo, vomiting, mental inactivity, and optic neuritis being general rather than local symptoms, and common to affections in any part of the brain, may of course be present in disease of the centrum ovale. It is not to these that reference is made, but rather to symptoms whose presence would lead inevitably to the diagnosis of disease below the cortex and above the basal ganglia. Nothnagel's assertion may be repeated to-day, notwithstanding the labor that has been expended since 1879 on the study of localized brain disease. It seems to me that the way to solve the problem here is to reason from anatomy and physiology to the probable results of lesion in the centrum ovale, and then in every case to examine for the symptoms which theoretically might occur. In that manner it will be evident that no latent symptoms will be overlooked, and it is not impossible that, after a time, so many new symptoms now unsuspected may be educed and brought into connection with lesions found by post-mortem examination, as to warrant the formulation of certain diagnostic signs of diseases of the centrum ovale. If the suggestions here offered regarding a possible symptomatology prove of service, my object will be attained.

SOME CONSIDERATIONS IN THE DIAGNOSIS AND PROGNOSIS OF ABDOMINAL ANEURISM.[1]

By A. A. SMITH, M.D.,

NEW YORK.

It is no uncommon thing to find at the post-mortem examinations cases in which death has occurred as the result of aneurism, and the aneurism very small. On the other hand, it is quite frequently found that a patient has died of an aneurism, the history showing the existence of such aneurism for a number of years, and the size enormous.

It is not always easy to explain why some persons tolerate an aneurism for a long time and to a great size, while others succumb in a short time and when the tumor is very small.

In many cases the diagnosis of aneurism affecting one of the large vessels of the abdomen is one of the easiest problems the physician is called upon to solve. If the physical signs are well marked, and ordinary care is observed in the examination, the diagnosis is easily arrived at; but in many cases the physical signs are obscure, or at least are not distinct. As all will testify, a growth lying across a large vessel in the abdomen may give rise to symptoms and signs so like those of aneurism, that the most skilled diagnostician cannot determine positively their significance.

In 1878, while I was one of the attending physicians at the Demilt Dispensary, Dr. Lockrow, another of the attending physicians, referred to me for diagnosis a case of abdominal tumor. The case had been seen by a number of physicians, and a variety of opinions had been expressed. The patient was a man, forty-three years old, intemperate, and an excessive smoker. He denied syphilis. His occupation, as long as he was able to work, was that of a farm-laborer. In 1873 he noticed a growth in the epigastric region, at first very small, but it gradually increased in size until, when I saw him, it nearly filled the whole epigastric space, especially to the right of the median line. He gave the history of repeated attacks of severe pain in the epigastric region, accompanied by slight fever, and severe enough to cause him to remain in the house, and sometimes to remain in bed. There had been but little change in its size after 1876, that is, two years previous to the time I first saw him. The tumor seemed to be pulsating, at least there was rise and fall with each pulsation of the artery; it was very irregular in outline. It was very hard and firm to the touch, and seemed, both by palpation and percussion, to be continuous with the right lobe of the liver. It seemed like a solid mass, very irregular in outline, quite

[1] Read before the Practitioners' Society of New York, January 8, 1886.

painful to the touch. There was no thrill and no distinct expansile pulsation. There was, on auscultation, a simple systolic bruit. The pulsation in the lower extremities was not as forcible as one would expect in a healthy person, yet it could hardly be called feeble. There was no change in the position of the tumor when the patient was placed in the knee-chest position. After three careful examinations, and excluding as well as I could its connection with any of the viscera, liver, stomach, intestines, pancreas, or abdominal wall, I concluded it was an aneurism of the abdominal aorta. I had seen within a short time a few cases of both thoracic and abdominal aneurism at the autopsy room at Bellevue Hospital, in which there was very great thickening of the serous coverings as the result of pleuritis and peritonitis. In the cases of abdominal aneurisms the tumors were matted together with the surrounding viscera by the much thickened peritoneum. It occurred to me that the patient I was examining may have had frequent attacks of peritonitis, and the peritoneum becoming much thickened in some places over the tumor, and less so in others, thus accounting for the irregularity in outlines. By careful questioning the fact was elicited that two months before he noticed the tumor he was kicked in the abdomen by a colt, and was, at that time, confined to the house for two weeks, but had never connected the two—the kick and the tumor. The frequent attacks of pain and fever were probably due to peritonitis. He died about one year later. Dr. Lockrow made the autopsy. There was an aneurism just below the cœliac axis as large as a new-born child's head, very irregular in shape, very thick layers of peritoneum over it—in some places much thicker than in others. Where the peritoneum was thickest there was least enlargement. Where the peritoneal covering was least marked, the tumor had expanded much more, and in some places pouch-like expansions had formed, making great irregularity in outline observed during life. While the peritoneal thickening obscured the diagnosis it seemed to me it played a very important part in the prognosis. It will be noticed the patient lived six years after the first discovery of the growth. Is it not probable that this very thickening of the peritoneum and the strong adhesions aided in the protection against rupture? Will not this very protection made, by the thickening of the serous covering as the result of inflammations, account, in many cases of both thoracic and abdmonial aneurism, for the much greater tolerance shown by some than others? I am well aware there are many factors which enter into the prognosis in any given case of aneurism. One of the dangers is from rupture. If the serous covering becomes very much thickened and covers the whole tumor, thus protecting it from expanding because of its over-weakened walls, it would seem quite probable this one danger, rupture, is delayed, even in some cases very much delayed.

I have a patient now under observation at the Bellevue Hospital whose history, and to a certain extent whose physical signs, illustrate this point in prognosis. It is a female, aged twenty-seven, a cook. She was in good health up to five years ago. At that time she had some uterine disease which kept her in bed five weeks. After her recovery she noticed a "sore spot" in her abdomen, just above the umbilicus. The pain in this sore spot gradually increased, and soon she noticed a small tumor in this situation which pulsated. Four months after this she entered one of the city hospitals, with very severe pain, which confined her to her bed for some weeks. She remained in the hospital over a year. Upon leaving the hospital she was free from pain, and her general health was good, although the tumor had increased in size and still pulsated. Nine months afterward she had another attack of severe pain, which caused her to remain in bed three months. At the end of fifteen months she had another attack of severe pain in the epigastric region, and was confined to bed for over a month. She remained comparatively free from pain after this until January, 1885, when another attack of severe pain sent her into Bellevue Hospital, where she remained in bed three months. She left the hospital April 1st, but returned May 19th, with still another attack of severe pain, and is in the hospital now. During all this time the tumor was steadily increasing in size, and the pulsation has become more noticeable. She denies syphilis and intemperance. She does not remember to have received any injury to account for the tumor.

There is a large, irregular-shaped, pulsating tumor in the epigastrium, just above the umbilicus, and over a surface two and one-half inches by three inches very distinct pulsation can be seen and felt. The expansile pulsation, so characteristic of aneurism, can be felt over this surface, and nowhere else over the tumor. Over the remainder of the tumor the surface is somewhat irregular and quite firm to pressure. There is no thrill and no murmur. There is no change in the position of the tumor when the patient is turned to one side, nor when put in the knee-chest position. The repeated attacks of pain were probably due to peritonitis, and with each attack the peritoneal covering has become more thickened. Over the surface where the distinct pulsation can be seen and felt the peritoneal covering is probably quite thin.

CONTAGIOUS OPHTHALMIA IN INSTITUTIONS.

By RICHARD H. DERBY, M.D.,

SECRETARY [illegible]

THE care and maintenance of dependent children is a duty which no community can disregard. Whether the beneficiaries have in the course of nature been deprived of their natural guardians, or whether in the struggle for existence, through lack of means for their support, they have been given up by their parents to others to care for, or whether, to save them from cruelty and neglect at the hands of those who should provide for them, the courts of law have interfered for their relief—whatever the history of the individual case may be, common humanity demands that a home or asylum should be provided for those helpless to look after themselves.

Either as objects of private charity or supported out of the public fund these children must be maintained. During the helpless years of child-life they must be housed, clothed, fed, and cared for in such a way that they shall become self-supporting. For the home or family life which has been denied them a substitute must be found. In every community the asylum or residential school for the care of dependent children has become a recognized necessity. In one way or another the support of such asylums falls upon the community in which they exist. Let us now consider what the duties of the city or State are in maintaining the charge of such children. That they may become self-supporting, and cease to be a burden upon the community in which they are to live, they must first of all be brought up with due regard to the laws of health, they must be trained to some useful pursuit that they may take their part in the battle of life. These propositions are so self-evident that it seems commonplace to insist upon them.

In an experience of many years as officer of one of the largest ophthalmic hospitals of the country, the writer has over and over again had children brought to him from some of our city institutions with their sight irreparably damaged, and with the sad statement, doubtless true, that before they were taken from their homes their eyes were perfectly sound. Annually in some of the asylums of the city and State of New York there are

[1] Committee appointed [illegible] consisting of Drs. [illegible] Derby, [illegible] John T. Mitchell, and Messrs. [illegible] Gallatin.

eyes lost, and children consigned to our blind asylums to be cared for their life long. Let us verify this last assertion before going any further.

Mr. William B. Wait, Superintendent of the New York Institution for the Blind, under date of January 27, 1886, writes as follows: "As we receive only those who are already practically blind, and as our work is strictly educational, and not curative, it is not essential for us to inquire into the cause or specific nature of the cases, or concerning the progress of the disease, or of the habitat where blindness supervened. I have, however, often had occasion to remark cases which have apparently originated in custodial institutions. It must sometimes happen that the committed children are suffering from eye disease when committed. An examination for a few years back gives the following result:

	Cases.
Randall's Island Nursery	11
Nursery and Child's Hospital, Staten Island	6
Roman Catholic Protectory	11
Foundling Asylum, 50 West Sixty-eighth Street	2
St. Joseph's Home, 65 East Eighty-first Street	2
House of Industry	2
Hebrew Guardian Society	1
Convent of Mercy, Newburg	1
St. Patrick's Asylum, Prince Street	1
Orphan Asylum connected with St. Peter's Hospital, Brooklyn	1
Dominican Sisters, Rockland County	1

"In one case the first eye was lost on Randall's Island and the second one at the Protectory; in another the first eye was lost at the House of Industry and the second one on Randall's Island. It is the duty of establishments which have the care of children to seek information and instruction on this subject, and to receive cheerfully, and enforce with care, such regulations as will prevent the inception and, when they do occur, the spread of eye diseases."

With a view to studying the conditions under which the dependent children of this great city are maintained, the asylums and residential schools have been visited. The local Board of Health has detailed medical inspectors for this purpose who have studied and reported on the construction of the institutions and the physical condition of the inmates, the method adopted for ventilating and heating the buildings, the plan and condition of the plumbing, the per capita allowance of air in dormitories and living-rooms, the construction of lavatories, the quality and quantity of food and clothing, the provision made for the treatment of contagious disease, and the care exercised in the reception into the institution of cases already afflicted with contagious disease; all these subjects have received careful attention, and the results of these investigations have been detailed in carefully prepared reports, an abstract of some of which accompany this preliminary statement and others are in process of preparation.

In connection with these inspections, conducted by sanitary experts, a committee appointed for this purpose by the New York Academy of Medicine has secured the services of men skilled in the treatment of diseases of the eye to accompany the inspectors of the Health Board, with a view to study the condition of the eyes of all inmates of these asylums. These ophthalmic surgeons, whose names are well known to the profession of the State and the country, have visited the fifty and more asylums of New York city and its vicinity. Drs. Agnew, Noyes, Loring, Roosa, Bull, Gruening, Pomeroy, Pooley, Callan, Andrews, Webster, Mittendorf, Emerson, Oppenheimer, Barker, Moore, Dennett, Isham, Lewis, Huntington, Hepburn, Carey, Bowles, and Ring have made careful investigations, and some of their reports accompany this brief informal statement.

These reports show, in the first place, the existence, in the asylums and residential schools which have been visited, of a disease of the eyes which can receive on the present occasion only a brief description. Contagious ophthalmia is characterized by an inflammation of the lining membrane of the eyelids, and a subsequent extension of the diseased process to the eye itself. From the parts affected there is a secretion, and this secretion is contagious. The secretion may be conveyed to healthy eyes by the water used in washing, by the towel or handkerchief, or even the air itself may be the bearer of the contagium. One peculiarity of the disease is that it may exist for months, and even years, in eyes which to the lay attendant, and even by the patient afflicted with it, have been thought to be perfectly healthy. In the case of some, if the subject is robust and the hygienic surroundings good, the eyes may escape without serious damage. In the case of many, after the disease has for a varying length of time been confined to the eyelids, it extends to the delicate structures of the eye itself, and the transparent cornea, or watch-glass covering of the pupil, becomes affected. The sight now is dimmed, ulceration or erosion of this membrane occurs, and, as a result, it is either permanently damaged or completely lost.

Of the dependent children cared for in the asylums of New York City, investigation has shown that one out of every four has contagious eye disease. It by no means follows that all institutions show so large a percentage of disease as this. As the reports will show, there are asylums where none or very few cases were found. There are, on the other hand, asylums in which more than half of the inmates have to-day eye disease of a very severe and dangerous type, and where, as the ophthalmic expert says, "it is a marvel to me that there is a healthy eye in the establishment" (report on St. Joseph's Asylum by Drs. Roosa and Ewing). The reports already received show many cases where one eye has been seriously injured, and many where the sight of both eyes has become permanently impaired.

Let us now see what light these reports throw upon the cause of this so generally prevalent eye disease, and what conclusions can be reached upon the proper methods to be adopted to stamp out so grave an evil. In the first place, as to the introduction of the disease from outside of the institution. Are the eyes of children and employees suffering from contagious ophthalmia examined before admission to the asylums? Let us examine our reports. Dr. Agnew tells us that in the Roman Catholic Orphan Asylum, at Madison Avenue and Fifty-first Street, the eyes of children are not examined before admission, and that the inmates of the institution who have diseased eyes are not quarantined. Dr. Roosa, who found in St. Joseph's Asylum 304 children, of a total number of 521, with diseased eyes, states that the eyes of the children are not examined before admission, and that no adequate quarantine is practised. Testimony of like character is furnished by many well-known authorities. Here, then, is a most prolific source of trouble, and to stamp out a disease so full of danger to the eyes of all housed in these institutions a rigid scrutiny of the condition of the eyes of all new-comers must be enforced.

Would it not be thought an evidence of criminal neglect if in an asylum provided for the young cases of scarlet fever, diphtheria, or small-pox were received and after reception allowed to come in contact with healthy children? What shall we say of the negligence of the board of management of an asylum which receives applicants suffering from contagious eye disease and provides a common dormitory, lavatory, and living-room for such cases, as well as those whose eyes are as yet healthy? Our reports give abundant evidence that such neglect as this is common. In many asylums all children who come, whether committed by the courts or brought by their guardians, are received by the non-medical attendants in charge of the institution. No medical examination of the applicant is made. The child, often suffering from disease acquired in its overcrowded, unhealthy tenement-house home, is assigned its bed in the already crowded dormitory. In common with other children, it is washed in the same lavatory, in which eigh-

teen children are provided with two or three towels per day (report of Drs. Loring and Stillwell). Have we not here at hand an explanation of the rapid spread of contagious ophthalmia?

It is not claimed that such a condition of things as this obtains in all asylums, but that the picture is not overdrawn we have the authority of Drs. Loring and Stillwell, Roosa and Ewing, Gruening, Callan, Andrews, and many others. How are evils such as we here recognize to be corrected? In the first place we hold that in each asylum and residential school of the State a medical officer should have discretion to receive or refuse to admit children. The responsibility for the sanitary condition of the building and of its inmates should properly rest with him. Each applicant for admission should be examined by such physician. No child suffering from contagious disease should be received. All children when received should be kept in quarantine for a reasonable period of time until it has been demonstrated that they are fit inmates of the asylum. More than this, it should be the duty of the medical officer to make frequent inspection of the institution and of all assembled there and report upon the same to the local Board of Health. This medical inspection should be thorough. First of all the dietary of the children should receive attention. Is the food-supply of the right character and sufficient? What do our reports say? In an asylum which shows perhaps the largest percentage of eye disease of any in the city Dr. Ewing tells us that in the nursery eighteen of the younger children had two quarts of milk per day—not two quarts each, but two quarts for the eighteen. We have the high authority of Dr. Agnew for saying that in one of the best-known asylums of the city the dietary is insufficient in both quantity and quality.

Again, the medical officer should examine the condition of the plumbing, sinks, water-closets, urinals, privies, and dormitories. That there is grave need for such inspection our reports give us abundant evidence. In the male branch of the Ladies' Deborah Nursery and Child's Protectory, Health Inspector Stillwell tells us, "the plumbing and lavatory accommodations are of the poorest kind. The urinal and school sink in the yard are dirty and offensive. In the cellar an abundance of rubbish, a dead cat, and a leaking Croton water-pipe saturating the earth surface with moisture. . . . The screw-cap of sewer-trap in cellar was off and gases freely escaping, also a drilled hole in the iron sewer-pipe adjoining this trap was open, allowing also an escape of gases. In the laundry (basement floor) the joint of tub waste-pipe with main waste-pipe was open, and the same condition occurred on the second and third floors, where within four feet of the children's beds the joints of sink waste-pipes were found open and the traps of said sinks unsealed by evaporation from disuse. . . . The lavatory accommodations are of the worst kind. In the extension on the first floor is a small room containing two bath-tubs, water is carried from here to the dormitories where the children wash in basins. In the nursery are eighteen children, to whom is allotted daily only three (and sometimes two) towels. On the beds one sheet was found, and in many instances this was dirty."

Again, in St. Joseph's Asylum Health Inspector Ewing reports: "The lavatories are very defective, being the trough and spigot plan, with a separate towel for each child, but the towels are hung in a row, with only four inches space between the towel-hooks, so that the towels themselves lie in contact."

In St. Joseph's Industrial Home, Dr. Stillwell reports: "Each child is given a towel daily, which, after use, is collected and dried without being washed, and oftentimes the same day is distributed to others."

In the New York Juvenile Asylum Dr. Stillwell states: "An objectionable feature of the plumbing work is that the water-closets and urinals thereto are in compartments that project into the general area of the dormitories. In some instances the urinals are poorly flushed, and the woodwork about them has become sufficiently impregnated with urine as to yield strong ammoniacal odors. . . . The boys' laboratory is supplied with running water and thirty-five roller towels daily for six hundred and fifty boys."

Especially should the medical officer examine and report as to the physical condition of the children and the existence of any contagious or infectious diseases, especially of the eyes or skin.

In St. Patrick's Orphan Asylum, female branch, Dr. Agnew found 203 cases of communicable eye disease among 409 children examined; of these 2 children had one eye and 22 both eyes seriously injured. In the male branch of the same institution, of the 357 inmates Dr. Noyes reports but 105 children with healthy eyes.

In the Ladies' Deborah Nursery Dr. Loring found, among 223 children, 50 suffering from contagious ophthalmia.

In St. Joseph's Asylum Dr. Roosa examined 521 children. He reports: "Contagious ophthalmia exists in all the classes of this Asylum. Its most severe form is seen among the younger children, although it exists among all. . . . No adequate quarantine is maintained in this asylum for those affected with contagious ophthalmia. Eight children had one eye seriously injured."

At the St. Joseph's Industrial Home Dr. Gruening reports: "I found 605 girls, ranging in age from three to sixteen years. Among these girls were 137 cases of chronic conjunctival blennorrhœa, making a percentage of 22.6 per cent. There were three children with one eye seriously injured, one with both."

In the Nursery and Child's Hospital Dr. Pomeroy reports: "Of the 461 children, 283 had perfect eyes and 178 had eyes more or less affected. Of the 64 adults, 14 had diseased eyes."

In the Mission of the Immaculate Virgin Dr. Pooley states: "Of the 372 boys examined, 127 were found with one or both eyes affected by contagious ophthalmia, making 34 + per cent. This number includes cases of all grades of the disease."

In the Catholic Protectory, of 2,137 children, Dr. Mittendorf found 871 afflicted with the disease, more than forty per cent. of the entire inmates. Dr. Mittendorf writes: "The cases were more frequent among the older inmates, and the longer a child remains at such a place the more liable it is to get the disease. . . . The principal cause is carelessness in admitting children that have diseased eyes and neglect to treat those that are diseased. Of the 871 children that I have examined and that ought to be treated, not one was properly attended to, nor were they isolated from the rest. The superintendent pretends to examine the children before they are admitted, but he must surely overlook many cases of granular lids, for three children were shown to me that had been admitted only a few days before I saw them, and they were afflicted with a most severe contagious form of granular lids; they were in the school-rooms and not isolated."

In the Five Points House of Industry Dr. Webster reports: "I found 155, or about 66.5 per cent. of the children affected with conjunctivitis in its various forms. . . . The worst cases, to the number of 26, were under treatment by the house physician in the eye wards." Dr. Webster found no evidence that the remaining 134 received any treatment whatever.

In the House of Refuge, at Randall's Island, Dr. Dennett found among 752 children 122 cases. He states: "The inmates wash thrice daily under running water, using about one hundred and twenty towels, which are changed every other day. Children with diseased eyes are admitted."

Dr. Andrews says of his examination of the Hebrew Sheltering Guardian Society: "The eyes of children are not examined before admission. Children with diseased

eyes are not quarantined. In the house at 360 East Fifty-seventh Street, are 76 children, 17 of whom have contagious eye disease. But there are really only 35 healthy eyes in the house; the remaining 24 children furnishing evidence in their eyes of the result of overcrowding and lack of proper breathing-space. Among 34 children there are but twelve towels, which are changed three times weekly.

At No. 320 East Fifty-seventh Street, which is a branch of the above-named institution, is a small, badly ventilated house; three children use the same towel, and ten children bathe in the same water. Here there are 52 children and 35 cases of contagious eye disease. There are also cases of contagious scalp disease (favus) among these children, who use the same hair-brush as the healthy children do.

"The percentage of contagious eye disease is most conspicuous in these two buildings, and while the floors and bedding are all that can be desired, and the people in charge seem to aim at making the children in their care comfortable and healthy; owing to their ignorance of the simplest rules of domestic and personal hygiene, they neutralize the good done in one direction by neglect in another. For instance, the rooms and bedding are clean and the food good, but the ventilation is very poor, and children with healthy eyes and others with diseased eyes play together, use the same towel, and wash in the same water. In conclusion, I desire to emphasize the circumstance that *these children go to public schools*. The evil attending this regulation, I need hardly state, is a very great one and must be self-evident." In a branch of this same institution at Eighty-seventh Street and Avenue A, Dr. Andrews found among 182 children 42 cases. He writes: "In this institution the children with healthy eyes mingle with those who have diseased eyes. When eye troubles become serious they are quarantined. But the majority of the cases of contagious eye disease in this and kindred institutions show no signs of eye trouble to a casual observer, and the disease is evident only when the eyelids are everted. And so such cases pass unnoticed, and spread the disease among the children, both in the institution of which they are inmates and in the public schools which they are permitted to attend."

The perils resulting from a neglect to quarantine cases of contagious disease occurring among the inmates of one of these asylums is well illustrated in Dr. Oatman's report on Mount St. Agatha, at Nanuet. In it he says: "Only three working sisters were in charge. Instead of limiting the number of children to forty, over one hundred, or all that could be secured, were taken. No physician was employed, but the writer visited the asylum weekly or oftener. Of the children admitted two only suffered from conjunctivitis. These were cases of chronic granular lids. The majority of these children were under four years of age, and during the entire winter and spring they were kept huddled together in the lavatory and passage leading to the water-closets. This was kept at a temperature of at least ninety degrees most of the time. The children never enjoyed out-of-door exercise. As the winter advanced cases of mild conjunctivitis appeared. These cases were taken to an old farm-house on the premises, as was any other case of sickness that developed; but no systematic quarantine or treatment was practised. Advice was resented and warnings of approaching danger laughed at. Dr. Agnew visited the place in May, 1885, and gave earnest advice in regard to the isolation of certain cases. This was unheeded. About this time I discovered in the old farm-house a case of malignant diphtheria among the children. I pronounced it such and gave most positive directions, but the managers deciding that it was mumps, did not pay any particular attention to it. Within one week ten children died from diphtheria. Two weeks later I visited the asylum and found thirty-two children in bed with fully developed purulent conjunctivitis. At this time I was employed to treat the disease. During the summer of 1885 I treated fifty-six cases of violent purulent conjunctivitis. Although several had a membranous form of the disease, one only had positively the diphtheritic form. This was fortunate, as diphtheria was at this time epidemic in the asylum. Several cases had, as is usual in such epidemics, been sent to Randall's Island for treatment. Two of these have since returned, each with one eye totally destroyed. Among those treated at Nanuet one eye was entirely lost. Two others suffered perforation of the cornea with resulting opacities. These accidents all occurred at one time, during the latter part of the epidemic."

After this sad story of neglect and culpable ignorance on the part of the board of management, let us see what careful management and the application of certain well-understood rules of preventive medicine can accomplish in dealing with contagious disease. In Dr. Emerson's report of the Sheltering Arms it will be seen that among 147 children 10 cases of conjunctival disease were found. Of the earlier history of this same institution, Dr. Pooley, its ophthalmic surgeon, writes: "The following account of an outbreak of contagious ophthalmia, which occurred in this institution, the measures resorted to to stamp it out and to prevent its return, I am enabled to give from my own and the matron's recollection of the facts. It began in October, 1872, soon after the admission of a girl with chronic trachoma, who shortly after her admission had an acute exacerbation of a purulent type. In a very short time there were 12 bad cases of purulent ophthalmia. Soon after this I was asked by the trustees to visit the institution, and found at least twenty cases of blennorrhœa of a severe form and nearly one hundred of a milder type. For several months I visited the institution as often as twice or three times a week, treating all the cases, and isolating the worst of them in a small building which was put at my disposition for this purpose. The disease lasted for ten months or more, and finally it became necessary to dismiss three or four cases, which were treated daily in the Dispensary of the Ophthalmic Institute in Twelfth Street. We were now comparatively free from the scourge, and from this time forth the following precautions have been rigidly observed:

"1. I examine the eyes of all children before admission, and none can enter without my certificate.

"2. If any child shows the least symptoms of eye disease we isolate him and treat him.

"3. We teach nurses and children to *watch* for it, and it is an unpardonable crime to use a towel, pillow-case, or handkerchief that belongs to any other child.

"4. I make it a point to visit the institution as often as I can, and to inspect the eyes of all the inmates, and Miss Richmond sends all suspicious cases to me for inspection.

"The cases mentioned in this report as at present in the institution are all receiving my attention."

Up to the present date, February 2d, returns have been received from 32 asylums, containing 10,264 inmates; of these, 3,322 had contagious ophthalmia, making 32 + per cent.

Our reports further show that many of the asylums are overcrowded. There are institutions where, in the dormitories, there is for each child less than one hundred cubic feet of air-space.

To meet the exigencies of the case the committee on contagious eye diseases is satisfied that legislation is needed, and to that end "an act for the better preservation of the health of children in institutions" has been drawn up.

The proposed act provides that every incorporated institution in the State receiving or caring for children (excepting hospitals) shall have attached thereto a regular physician in good professional standing, who shall carefully examine each child applying for admission to the institution, and shall give a certificate in writing, stating whether or not the applicant is suffering from any contagious or infectious disease, especially of the eyes or skin. No child suffering from any contagious or infectious

disease shall be allowed to enter or remain in any institution in contact with children not so affected, but shall be immediately isolated, or placed in a proper room or infirmary, which shall be provided for that purpose. It is made the duty of the physician to give notice in writing to the officers of the institution whenever any dormitory therein is so overcrowded that there shall be afforded less than six hundred cubic feet of air to each occupant. He is also to report regularly to the local Board of Health in regard to the sanitary condition of the premises.

Progress of Medical Science.

Habitual Abortion and Kidney Disease.—Dr. Fehling, some months before his death, read a paper on habitual death of the embryo in kidney disease. In the first case under his observation premature expulsion of a dead fœtus occurred six times, and there was no evidence of syphilis. At every pregnancy anasarca, albuminuria, and death of the fœtus, with severe cramp of the abdominal muscles, occurred between the fifth and sixth months; the dead fœtus was expelled from three to ten weeks later. In the second case similar symptoms appeared in a young unipara; the fœtus died, and thereupon the albuminuria abated. In the third case the patient had borne two healthy children. During her third pregnancy albuminuria and characteristic changes in the retina occurred, and during the fourth she was seized with hemiplegia; in both a decomposed fœtus was expelled at the fifth month, with subsequent decrease of the albuminuria. In the fourth case the patient, in her first pregnancy, aborted at the fifth month; then she gave birth at term to a recently dead child. In the third pregnancy great œdema and albuminuria supervened, the child was still-born, and the mother died of uræmia. Dr. Fehling believed that, in all these cases, kidney disease existed before pregnancy, which aggravated the renal symptoms. Winter had described two cases of premature detachment of the placenta, normally situated, where albuminuria existed. Dr. Fehling found atrophy of the villi of the chorion, with wedge-shaped or spherical infarcts in the placenta, in his cases, similar to renal infarcts. The infiltration of the chorionic villi and vessels of the umbilical cord with small cells, as seen in syphilis, was absent, nor did any of the embryo exhibit a trace of congenital syphilis.—*British Medical Journal*, November 21, 1885.

Ox-Gall in Typhoid Fever.—Dr. Samuel Lloyd reports that since the publication of the paper on "Ox-gall in Typhoid Fever," in the first number of this journal, he has had an opportunity of personally observing its action, and has found that the results obtained were similar to those claimed by Dr. Van Schaick. The temperature in his case, before the administration of the ox-gall, was ranging above 105, but after the exhibition of the drug it was successfully kept below 102, while all the symptoms gradually assumed a milder form. The preparation used was the Fel bovis inspissatum, which was administered in capsules of five grains each every two hours, unless an exacerbation occurred, when it was given more frequently. The taurocholate of soda was substituted at one time, but its action was very unsatisfactory, and a persistent increase in the diarrhœa and range of the temperature compelled a return to the former preparation.—*Quarterly Bulletin of the New York Post-Graduate Medical School.*

Abolition of the Patellar Tendon Reflex in Diphtheria.—The following are the conclusions of M. Bernhardt in an interesting paper on this subject appearing in *Virchow's Archiv*: 1. In a large number of diphtheritic affections there is observed an abolition of the patellar tendon reflex coming on some weeks after the attack, even in mild cases and in those which have been followed by no other paralytic symptoms. 2. The appearance of this sign some five weeks, more or less, after an attack of diphtheria should make the physician cautious in his prognosis concerning paralysis. 3. The absence of the patellar reflex may continue for five or six months and more, and in some instances the author was unable to assure himself of the return of the phenomenon to its normal degree. 4. Bernhardt admits that this symptom may be due to some nervous lesion of parasitic nature, and concludes by comparing the loss of the reflex occurring after diphtheria with the same sign when found in the initial stages of locomotor ataxia.

Salicylate of Lithia in Rheumatism.—In a paper read before the Academy of Medicine of Paris, on December 8, 1885, M. Vulpian gave the results of a number of experiments with salicylate of lithia, which he had found to be of great service in the treatment of all the forms of rheumatism. He said it was a mistake to suppose that the salts of lithia possessed any remarkable toxic properties: they were no more so than the corresponding salts of other bases, and the salicylate could be given in nearly as large doses as the salicylate of soda. In cases of acute rheumatism, joint pains, sometimes of very severe character, often persist for a long time after the swelling of the articulations has subsided. Salicylate of soda as well as tincture of colchicum have but little effect in quieting these pains, but salicylate of lithia, M. Vulpian said, causes their rapid disappearance. The drug acts especially well in those cases in which the fibrous tissues are affected. In the subacute and chronic forms also salicylate of lithia acts more promptly than the sodium salt. The drug should be given in doses aggregating one drachm per diem, but when more than seventy-five grains a day are given, toxic symptoms are apt to be produced. It causes headache and deafness, but never the whistling and ringing sounds in the ears which cause such extreme annoyance to the patient. Sometimes also, though rarely, intestinal colic and diarrhœa result. But all these unpleasant symptoms disappear quickly after the discontinuance of the remedy.

Iodol, a Substitute for Iodoform.—Iodol ($C_4 I_4 NH$) is the name that has been given to a new antiseptic recently introduced into use in surgery. It is described as being tetra-iodo-pyrrol, and is said to be prepared from pyrrol, obtained from animal oil, and made moderately pure, by precipitating it with a solution of iodide of potassium containing iodine. In appearance it is a light-brown powder, which under a lens is easily seen to be crystalline. It has a faint odor resembling thymol, but no taste. It is nearly insoluble in water, soluble in hot fixed oils, in three parts of alcohol, and freely in ether and chloroform. It is not precipitated by glycerine from the alcoholic solution. At 212° F. it gives off the vapor of iodine. The great advantages claimed for it are that it contains ninety per cent. of iodine, and has not the disagreeable persistent odor of iodoform. More than two hundred observations on various diseases have been made with it in the Royal Surgical Institute in Rome. It was used suspended in glycerine, dissolved in alcohol and glycerine, and as an ointment. Chancres were washed with water, dried, and then sprinkled with iodol powder and covered with silk-protective, the dressing being changed daily. In six days' time the base of the chancre began to granulate, and the edges to show signs of commencing cicatrization. Under like treatment open buboes soon improved and healed up. With single indolent ulcers it proved equally valuable. On the other hand, the remedy is found useless, and indeed harmful, in gangrene. Further, it is found to possess the power in a high degree of promoting healthy granulations, as is shown by its use in various forms of lupus and in chronic fungoid inflammation of the joints.

Oxygen has been found, by Prof. Laschkewitch, to be of benefit in hysteric and hystero-epileptic attacks. He thinks that it lessens nervous excitability.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 13, 1886.

CONTAGIOUS OPHTHALMIA.

THE article by Dr. Derby, published in our columns this week, is virtually a review of the investigations made this winter by the Committee on Contagious Eye-disease appointed by the New York Academy of Medicine. This committee, consisting of well-known members of the Academy and representatives of the Society for the Prevention of Cruelty to Children, the State Board of Charities, the State Charities Aid Association, and the Society for Improving the Condition of the Poor, have caused all the asylums for the care of children in New York City and its vicinity to be visited. Together with inspectors detailed by the Board of Health, well-known ophthalmic surgeons have examined the eyes of the children and studied the causes of the alarmingly prevalent contagious eye-disease. Among the many startling facts elicited by these investigations none is more significant and full of meaning than this: That a group of thirty-nine children are to-day in the New York Institution for the Blind, who, during the past few years have been sent there from some of our best-known and most generously supported asylums. Children between the ages of six and sixteen are very unlikely to suffer from non-contagious eye-diseases entailing blindness, and blindness in children is very rarely the result of contagious disease which has received proper care and treatment. These children, wards of the city and State, were placed in the several asylums to be brought up with healthy bodies and taught some useful trade, that they might become self-supporting—to-day they are blind charges of the State. The report to which we have referred points out in language that cannot be mistaken that these blind children lost their sight through neglect of the simplest rules of hygiene and health on the part of those who should have cared for them. By the testimony of many competent witnesses the report shows that in many asylums of this city children with contagious eye-disease are received, and that the healthy eyes of children already there thus speedily become affected. The report shows gross carelessness in allowing healthy and diseased children to use the same roller-towel and wash in the same water. It shows an absence of any proper system of quarantine of children who are manifestly the bearers of contagium. It shows an entire laxity of medical care in providing healthful dwelling-places or proper treatment where it is sorely needed. To meet these and other evils the committee has prepared a bill for "The Better Preservation of the Health of Children in Institutions," and has secured the introduction of the same in the Legislature at Albany. This bill throws the responsibility for the medical management of the asylum upon its medical officer, and provides that he shall make frequent inspection of the institution and of its inmates, and report upon the same to the Board of Health. The bill provides that no child with diseased eyes or other contagious disease shall be admitted, and calls for an efficient quarantine of all children in the asylum who may become affected with contagious disease. It declares a neglect to carry out these provisions of the bill to be a misdemeanor. This is eminently wise legislation, and is going none too far. THE RECORD has already on other occasions urged the great importance of adopting stringent rules and regulations at our asylums to protect the inmates against a disease which entails so often such disastrous consequences.

"INSTINCT AS A GUIDE TO HEALTH."

AN interesting article with the above title appears in the February number of the *Popular Science Monthly*, from the pen of Dr. Felix Oswald. He briefly sketches the hygienic advances which have been made in the last two hundred years, and attributes them, as well as educational and social reforms, to a "restored trust in the competence of our natural instincts;" in other words, "many of the hygienic reforms of the last two hundred years could have been anticipated by the simple teachings of our senses." Many of the evil manifestations of our natures—the moral depravity of the theologians—are to be regarded not as the remains of "old Adam," but rather as the expression of abnormal appetites artificially acquired.

Hence, then, true instinct is to be regarded as the guide toward right physiological living. The "ward of instinct," says Dr. Oswald, does not need a temperance lecture to counsel him to shun alcoholic beverages; the repugnance of nature to such ingesta is unmistakably expressed, and it is only by repeated trampling upon her advice thus expressed that the repugnance is overcome and transformed into an actual longing. The natural movements of the developing child are a greater proof of the necessity of exercise and a more convincing demonstration of its utility than any labored argument to show that exercise is beneficial.

What, then, has interfered with the establishment of that hygienic Utopia toward which true instinct would long since have led? The answer is, a perversion of instinct, a nursing of unnatural appetites. "In some exceptional cases," says Dr. Oswald, "nature fails to advise us of perils which her warning could easily avert," and he groups these exceptions under the headings of perverted instincts, abnormal perils, and parasitic disorders. The perversion of instinct is often of obscure origin, and when exercised in regard to the ingestion of any poisonous substance may become "vehement and persistent in proportion to the virulence of the poison." Persistent disregard of instinct will often bring about this result. As between instinct and perversion thereof, it becomes a contest for the survival of the fittest, and finally nature gives up the struggle.

In regard to abnormal perils, "the foresight of instinct" seems to be deceived "in a way typified in the non-repulsiveness of certain mineral poisons. Nature has taken ample precautions to secure her creatures against the poisons of the upper world—hemlock, foxglove, belladonna—but failed to provide safeguards against such subterranean evils as arsenic."

The existence of parasitic disorders seems to go against the theory of the healing instincts of nature. But the cause of these disorders is generally plainly visible, and can be directly removed, whereas the causes of other ("symptomatic") diseases "is often aggravated by the suppression of its external manifestations."

One notable exception is mentioned, apparently in opposition to the conservatism of Nature. It is the fact that at certain stages of pulmonary phthisis the sexual instinct is stimulated to a degree hardly compatible with the best result to the organism. Salacious manifestations at the late stage of phthisis are by no means uncommon. Here we are told this tendency comes only in a late and hopeless stage of the disease, when "nature sacrifices the interests of the individual to those of the species." In such cases as these instinct would not be a true guide. Yet, on the whole, it is to be trusted. The rejection of food by the overloaded stomach, the yielding of the tired body to sleep, the unrest characteristic of lung diseases—and relieved by fresh air—all these, and many others, show how truly the instinct indicates the successful plan of treatment. We are not to believe that "our protective instincts at the most critical moments become false to their mission, and urgently warn us against the means of salvation."

COMFORTS FOR MEDICAL MEN.

It is quite possible that medical men, who above any other professional class are subject to exposures and all the discomforts and dangers attending, do not provide as much as they might for their own comfort and safety. Medical fashions and habits control the physician to such a degree that he is liable to slip into the routine of his fathers, without thinking whether it might not be possible to effect improvements and alleviations in his lot.

For example, it is, we believe, quite unheard of for the rural physician ever to travel in anything but an open wagon, or the regulation doctor's gig. This latter affords some protection from storm and wind, but not a very great deal, and the main reason for its universal use is that it is light, and can be propelled at less expense to the horse. In England, broughams and hansoms are very much employed, even outside the cities. These of course require a driver, but there are many physicians for whom it would be an economy to avoid the risks and hardship of winter exposure by hiring an extra servant.

But even the doctor who must use the gig can often make it a more agreeable and comfortable vehicle than is now the case.

Mr. T. Pridgin Teale, who has been discussing this subject in *The Lancet*, writes:

"A medical man who visits his patients in an open gig or carriage, whenever he enters a house, leaves a warm seat, and on returning in ten or fifteen minutes finds the cushion and rug cold. By the time he reaches the next house the seat and rug are warm again, and out he gets, to let them cool down before his return; in other words, he is perpetually parting with bodily heat, which in severe weather he can ill spare, and is warming up, to very little useful purpose, inanimate material. This may be obviated by having either a hot-water bottle (of stoneware, not of metal), or one of the still more convenient india-rubber hot-water bags with a woollen cover. On his entering a house the warmer is placed on a cushion and is covered by his rug; it is placed at his feet when he returns to his carriage. If he drives in a brougham, or in a carriage in which the driver is not at his side, it is better that the hot-water bottle should be pushed to one side, or kept on the seat, protected by the rug."

Mr. Teale makes another suggestion, viz., that medical men who are liable to be called up in the night should always have a fire in their bed-room. We think that this is perhaps an unnecessary hint to the American doctor, who is not accustomed to sleep in a fireless room with the temperature thirty degrees below zero.

In driving in the cold it is very soon learned that the first essential to comfort is to keep the feet and the wrists and hands warm. This does not appear to have been learned by our English brethren, who doubtless do not often have such instructive temperatures as are experienced upon this side of the water.

THE LATE DR. ALFRED C. POST.

Few men ever leave such a record of untiring and conscientious industry in their profession as did the late Dr. Post. His professional activity covered a period of two generations, and when he died he had outlived all his early contemporaries. Dr. Post was remarkable for his activity and professional enthusiasm even to within a fortnight of his death. He carried on his surgical practice, performed operations, attended societies, discussed and wrote upon the living topics of the day, with all the freshness and zeal of youth. Age, he would say, is not a matter of years.

Dr. Post's most salient and admirable moral trait was his rigid sense of duty. To this he was always faithful, at no matter what sacrifice. He was a man of firm religious faith, devout in his behavior, and an excellent theologian and biblical scholar. The two things, he is reported to have said, which he enjoyed most were a surgical operation and a prayer-meeting. This at least expressed the two leading motives in his life: devotion to his profession and to the Christian faith. The example which he set, of a man who lived a thoroughly earnest, unselfish, and useful life, cannot fail to leave a beneficent influence which will last long after the tireless worker himself has gone.

THE QUESTION OF THE EXISTENCE OF "NEURASTHENIA."

Sir Andrew Clark has recently made some observations upon so-called "neurasthenia" which are not in the least novel, but which, coming from so eminent a physician, will attract attention. Sir Andrew states that the term neurasthenia has, despite just opposition, won its way into medical nosology, and now receives notice at the hands

of nearly all systematic writers on general or neurological medicine. This condition of affairs he regards as unfortunate, since the word neurasthenia is applied to a mob of heterogeneous symptoms, and does not represent to the mind any distinct clinical entity, nor have for its basis any uniform pathological change.

Sir Andrew Clark appears to believe that there is such a thing as nervous exhaustion or asthenia, but he does not find that the symptoms resulting from it have as yet been clearly recognized, or explicitly described and circumscribed.

There is no question as to the truth of the view which the distinguished physician takes. We, in America, who can, perhaps, best appreciate the evils which are referred to, have long ago recognized them. There is, beyond any question, a functional nerve-disorder which can only be designated as chronic nervous asthenia, since both the causation and the symptoms point to a dynamic weakness of the nerve-centres. But, unfortunately, these states of functional asthenia run so closely into those of degeneration and irritation, that the establishment and separation of the neuro-asthenic group of symptoms have been attended with difficulty and confusion. The late Dr. Beard greatly overloaded his subject, and Professor Arndt, of Vienna, who has just written an elaborate treatise on neurasthenia, has fallen into the same error. The latter, like Sir Andrew Clark, seems to think that all the neurotic people in the world's history, from Julius Cæsar to the poet Heine, may be classed among neurasthenics.

We understand that the more careful neurologists in this country find that there is a group of symptoms very characteristic and well defined, to which no better name than neurasthenia can be given. Therefore the term is still used, and it is increasingly prevalent.

THE DEATH OF GENERAL HANCOCK.

With the sad announcement of the death of General Hancock comes the somewhat startling statement that the disease, diabetes, from which he died, was only recognized a few days before his death.

While this latter statement may not be true, and we trust it is not, the case will, at any rate, serve to enforce the lesson of a more thorough examination of the urine in all chronic cases that come to the physician's care. We fear that there is too great a tendency among many busy practitioners to be content with a squeeze of the pulse, a glance at the tongue, and a few raps on the chest. The examination of the urine should be made a routine practice in all cases.

The Mississippi Valley Medical Monthly.—When a local medical journal and a local medical college fall out, the results are likely to be unpleasant for the latter. The *Mississippi Valley Medical Monthly*, which is ably edited by Professor F. L. Sim, has opened its controversial fires upon the Memphis Hospital Medical College. The sympathies of the on-lookers, on general principles, must be with the journal in such cases, since local medical journals are helpful to the profession, while local medical colleges are sometimes so, but not always.

News of the Week.

Cocaine is now only threepence a grain in England.

The Journal of Cutaneous and Venereal Diseases is now edited by Dr. Prince A. Morrow.

Dr. Paul F. Mundé gave a brilliant reception to the members of the New York Polyclinic on Thursday evening of this week.

The Cost of Small-pox to Tennessee during the past five years is estimated by the State Board of Health to be $141,619.91.

The Only Daily Medical Journal in the world is, we learn, *La Riforma Medica*, published in Naples by Professor Cav. Gaetano Rummo, and now in the second year of its existence.

Virginia has not over fifteen homœopathic physicians in the whole limits of the State. Yet a bill has been introduced into the Legislature to create a Homœopathic Board of Medical Examiners.

A Bill to Regulate the Practice of Medicine in the State of Maryland will be presented to the Legislature during its present session by a committee appointed by the Medical and Chirurgical Faculty of Maryland.

The Madstone.—A correspondent asks if there is anything in the "madstone" as a preventive of hydrophobia.—No, but it may be an excellent remedy for hysterics, following the bites of dogs. The madstone is a form of faith cure.

Portrait of Dr. John C. Dalton.—By invitation of a very large number of his friends and former pupils Professor John C. Dalton is to sit for a portrait, to be painted by Eastman Johnson, and subsequently presented to the College of Physicians and Surgeons.

Reducing the Income of the Health Officer.—A bill has been introduced into the Senate at Albany fixing the fees of the health officer of this port at $10,000 a year, with $3,000 for the first assistant, $2,000 for the second assistant, and $6,000 for the expenses of administration.

A Commission to Investigate the Question of the Prophylactic Inoculations against Yellow Fever.—Dr. Joseph Holt, President of the Louisiana State Board of Health, is in Washington, urging the passage of a bill creating a commission to investigate the alleged preventive inoculations against yellow fever.

Conception after a Double Ovariotomy.—Dr. Schatz reports a case (*Centralb. für Gynäk.*) of a young woman from whom he removed the whole of the left ovary for a cystic tumor; he also removed part of the right ovary, which had undergone cystic degeneration. The patient menstruated regularly, subsequently married, and in May, 1885, was delivered of a daughter at full term.

Wanting a Real Arm.—A correspondent, who is a layman, and evidently has lost an arm, writes in all seriousness, asking us if there is not some surgeon in New York bold enough to try and graft a new arm on his stump. He states that he is willing to pay a convict or any other person who might be willing to contribute his arm to the cause.

Monument to M. Bouley.—The Veterinary Society of Grenoble has voted to solicit subscriptions for the erection of a monument to the memory of the late Professor H. Bouley, to be erected in the Veterinary School of Alfort. Subscriptions are requested from veterinarians, physicians, and all men of science who have benefited by Bouley's labors.

Prohibiting the Sale of Tobacco to Minors.—A measure, supported by voluminous petitions, is before the Committee of the Massachusetts Legislature on Public Health, to restrict the sale of tobacco to minors under the age of fifteen or sixteen years. It is claimed by the petitioners that both boys and girls in the public schools are addicted to the use of cigarettes to an alarming degree.

"The Southern California Practitioner," is the title of a new monthly medical journal published at Los Angeles, Cal., and edited by Drs. J. P. Widney, Jos. Kurz, and Walter Lindley. The gentlemen are also members of the Faculty of a new medical college, called the College of Medicine of the University of Southern California. This institution, we are told, opens with prosperous auspices.

A Proposed New Medical College in North Carolina.—The *North Carolina Medical Journal* states that the project of establishing a medical college in connection with the University of North Carolina is being seriously considered. The *Journal* wisely insists that such a college should not be started until sufficient money is pledged or secured to make the faculty independent of students' fees.

The Way They Do It.—We are requested to state that the advertising homœopathist referred to in our issue of Janury 30th, is not a member of the Homœopathic Society in question, and that consequently he cannot be reached by that or any other society, unless possibly by first enforcing the law requiring membership in some recognized county society, as the law makes no provision for ethical misdemeanors. He was nominated for membership of that society, but the nomination was opposed in open meeting—because of the facts stated in The Medical Record—, and he was not elected.

Liability of Hospitals for Mistakes or Acts of Employés. — Malcolm S. Daly, aged seventy-four, recovered a verdict of $1,700 in the United States Circuit Court, at Omaha, Neb., against the St. Joseph's Hospital, conducted by the Franciscan Sisters. The facts proved that Daly, occupying a room in the hospital while under treatment for cataract by an oculist, one of the nurses, by accident or mistake, dropped carbolic acid in his eye, which entirely destroyed it. Daly was a paying patient.—*Medico-Legal Journal.*

The Decline of Iridectomy.—"We note," says the *Medical Press*, "that M. Panas, of Paris, in advocating a new ophthalmic antiseptic, boasts that he has been able to do away with Von Graefe's method of cataract extraction (linear incision with iridectomy) and revert to the older flap operation, reserving the iridectomy for exceptional cases. . . . Ophthalmologists have recovered from the iris-snipping craze, are convalescing from the jequirity fever, and are down in the cocaine epidemic. Shall we not look back on the literature of the iridectomy mania and profit by the proof since given, that nine-tenths of what was then written in praise of iridectomy was nonsense—that most of the statistics of cures were cooked and utterly unreliable, and that we retain at the present day nothing gained from the ophthalmological perfect cure except its occasional use as a forlorn hope?"

The New York Odontological Society gave its annual dinner at the Hotel Brunswick, on Wednesday evening of this week. About two hundred gentlemen were at the table, among them E. A. Bogue, President of the Society; William H. Arnoux, Dr. Fordyce Barker; Drs. Thomas M. Markoe, J. C. Hutchison; Professor R. R. Andrews, of Cambridge; ex-Postmaster General James, Dr. William A. Hammond; Drs. A. F. Beard and Ernest Bent, of Paris; Drs. James McManus and George L. Parmele, of Hartford; Drs. Abraham Jacobi, Lewis A. Sayre, Dr. George F. Shrady, and Dr. Norman W. Kingsley. General Horace Porter, in speaking of dentists from a patient's standpoint, said that it was the first time that he had fallen into the hands of dentists when he found his mouth in a condition for speech-making. Other speakers were the Rev. Dr. Howard Crosby, Dr. J. Smith Dodge, and Professor J. E. Garretson, of Philadelphia.

Criminal Liability of Ignorant Doctors.—A physician, called to attend a sick woman in Worcester, ordered that she be clothed in flannel saturated with kerosene oil, and that the saturation be renewed from time to time. The direction was followed, and caused the death of the patient. The doctor was indicted for manslaughter and convicted. The case was appealed to the Supreme Court of Massachusetts; that tribunal has just given an opinion sustaining the verdict. The doctor offered some evidence, on the court trial, that he had prescribed similar treatment, with favorable results, in other cases, but that in one the result had been to blister and burn the flesh. His counsel asked the trial-judge to charge the jury that if the defendant prescribed with an honest purpose and expectation to cure he was not criminally liable for the death of the patient, however gross his ignorance of the nature of the disease or the probable effect of the remedy; that he could not be convicted of manslaughter without finding him guilty of "obstinate, wilful rashness." The judge refused to so charge, and the ruling is affirmed by the Supreme Court. It holds that it is not necessary to show "an evil intent" on the part of the doctor. If by gross negligence, recklessness, or foolhardy presumption he caused the death, he was guilty of culpable homicide. The defendant professed to be a physician. A physician of the most ordinary knowledge and experience is expected to know the probable disastrous effect of the remedy prescribed in this case. "The man who assumes to act as the defendant did must have done it at his peril. The defendant knew that he was using kerosene and saw from day to day how it worked. The jury has found that it was applied as a result of foolhardy presumption or gross ignorance, and that is enough."—*Medico-Legal Journal.*

Malpractice Suits and Their Prevention.—Another unsuccessful suit against a doctor is reported in the *Daily Commonwealth*, of Covington, Ky. About one year ago J. B. Garrard jumped from a moving train on the Kentucky Central Railroad, at Catawba Station, and broke his leg above the knee. He was brought to St. Elizabeth's Hospital, in this city, and treated by Dr. Charles Kearns, the Hospital Surgeon. He remained there for over three months, and his leg was mending nicely, when, contrary to the doctor's advice, he went home, resulting in a set-back of his injury, which eventually resulted in a shortened leg, and he entered suit against Dr. Kearns for $10,000 damages. The case was tried in the Circuit Court yesterday and given to the jury, which only took a few minutes to decide in favor of Dr. Kearns. In this connection we may publish a communication received from Dr. W. S. Parker, of Piqua, Ohio, suggesting a remedy for the useless and malicious prosecutions to which physicians are subjected. He says: "I would suggest the framing and passing of a law, the force of which would be to put the plaintiff under sufficient bonds to indemnify, in case of failure to sustain his charge, the physician or surgeon for all pecuniary loss said physician or surgeon may have incurred, as well as a fair compensation for any loss of time. Several suits have fallen under my own observation; I was once jeopardized myself, and in each instance the suit failed. In my judgment, were some such law in force, but few suits for malpractice would be instituted."

Obituary.

ALFRED C. POST, M.D., LL.D.,

NEW YORK.

When it became generally known, a few days ago, that Dr. Post was confined to his bed with an attack of his old complaint, cystitis, his many friends were anxious as to the result. Although blessed with a vigorous constitution, he had, within the past few months, shown to his intimate friends signs of failing health. He pluckily kept to his work, however, and was apparently contented in his ability to do so up to the last. Happily, his suffering was of short duration, and his end was a peaceful one. He was one of the old landmarks for the profession of New York. In actual practice for fifty-seven years! Who are they in the present generation who can reasonably expect such a life-experience, and who can use it to better advantage? Every one knew Dr. Post. Thousands have heard him lecture, have seen him operate, and have read his published papers. Not to have done either would imply the missing of something. Indeed, he was a remarkable man in many ways. At the age of eighty he combined the enthusiasm and freshness of youth with the stolidity and discretion of ripe experience. No truth was too novel for him, no fact too old for him. As a lecturer he was always impressive, terse, and explicit; as an operator he was bold, steady, and self-reliant; as a writer he was lucid, logical, and classical. In fact he took a just pride, at his advanced age, of being precise in everything pertaining to his daily walk and conversation. His memory was something remarkable, and many who presumed to question it on general principles were often brought up with a round turn by a timely reference to a published fact or an apt quotation from some classic poet. His rich store of scientific and classical knowledge was always at his command, and those who knew him best respected his views the most.

Dr. Post was born in this city in the year 1805. He was the son of Joel Post, an eminent merchant of the old firm of J. & J. Post, formerly in Hanover Square. Joel Post in his lifetime occupied as his country-seat the property known as Claremont, now forming in part the Riverside Park and embracing the site of General Grant's tomb. Much of this property still remains in the ownership of the family. Dr. Post entered Columbia College when less than fourteen years old, and, in fact, was prepared to enter college two years earlier. After his graduation, in 1822, he became a medical student in the office of his uncle, Dr. Wright Post, an eminent surgeon of a former generation. He also took the course of instruction in the College of Physicians and Surgeons, where he was graduated in 1827. He then went to Europe to complete his medical education, studying at Paris, Berlin, and Edinburgh.

On his return, in 1829, he began the active practice of his profession in this city, and continued it until the week before his death. Dr. Post, as early as 1836, was made one of the attending surgeons of the New York Hospital, and more recently was connected with the medical staffs of St. Luke's and the Presbyterian Hospitals. He was one of the founders of the medical department of the University of the City of New York, taking the chair of surgery and pathological anatomy, and at the time of his death was President of the Medical Faculty and Emeritus Professor of Clinical Surgery in that institution.

He was also at the time of his death Consulting Surgeon to the New York and Woman's Hospitals. His connection with the former institution extended over a period of fifty-one years, and was to have been made by the Board of Managers of that institution the occasion of a jubilee the coming spring.

He was a member of the New York Academy of Medicine, serving it as Vice-President; of the Pathological Society (once its President), of the County Society, the Medical Society of the State of New York, and of many foreign societies. Actively interested in the prosperity of all, he was always ready to contribute to their transactions by valuable papers and remarks. Few men have held so many positions of trust, and few indeed have filled them with more credit to themselves. Dr. Post was a quiet Christian, one who gave evidence of the fact rather by his works than words. He was a lifelong member of the Presbyterian Church, and at the time of his death was an elder in the Church of the Covenant. He was also President of the New York Medical Missionary Association, and one of the Directors of the Union Theological Seminary.

About the year 1832 Dr. Post married Harriet, a daughter of Cyrenius Beers, whom he survived nearly nine years. Of their children, three sons and four daughters survive their father. One of his sons, George E. Post, of the Presbyterian Mission at Beirut, Syria, has also reached great distinction as a surgeon.

The funeral services were held on Wednesday, February 10th, at the Church of the Covenant, and were largely attended by his numerous friends.

The Rev. Drs. John Hall and George L. Prentiss were the officiating clergymen, and the latter delivered a touching eulogy upon the deceased. Delegations from the County Medical Society, the College of Physicians and Surgeons, the Academy of Medicine, and the Medical Department of the New York University were in attendance, and the Church was crowded with professional and other friends of the dead man.

The pall bearers were Dr. Abraham Jacobi, Dr. D. Lewis, Charles Butler, Maurice M. Backus, Dr. William N. Blakeman, Dr. A. L. Loomis, Dr. A. S. Purdy, Dr. Stephen Smith, Dr. Charles Inslee Pardee, Dr. George F. Shrady, William A. Booth, and Ezra Kingsley. The family physicians, Dr. A. E. M. Purdy, Dr. R. F. Weir, and Dr. R. Abbe, were also in attendance. The interment was at Woodlawn.

Reports of Societies.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, January 8, 1886.

BEVERLEY ROBINSON, M.D., PRESIDENT, IN THE CHAIR.

DR. GEORGE F. SHRADY presented a patient, the subject of

SPINAL ARTHROPATHY.

The patient was sent to him four years ago, for operation, on account of what was supposed to be a tumor of the left knee. On examination the joint appeared much enlarged, especially on its inner aspect, was very irregular in outline, and was in a condition of lateral subluxation. The articular surfaces were denuded of cartilage, and the ligaments were so lax that not only could lateral deflections be made with the greatest ease, but the tibia could be rotated to a considerable extent on its longitudinal axis. All these manipulations were painless, nor did the patient complain when steadying herself upon the limb, notwithstanding the fact that the denuded joint surfaces would grate and grind into each other in a way that seemed to threaten the crushing of neighboring bone structures. What appeared on superficial inspection to be a tumor, was an expanded, osteo-porotic inner condyle of the femur. Other bony parts of the joint were similarly affected, but not to such a symmetrical degree. The synovial sac contained no appreciable amount of fluid; in fact, the joint as a whole gave the impression of being in a condition of dry disintegration. The left leg, naturally large on account of the patient's obese condition, was much increased in size by fibrinous infiltration of the soft parts, and hyperplasia of the osseous tissues. The condyles and lower third of the femur were similarly affected. At first he concluded that the case was an unusually marked one of rheumatoid arthritis, but inquiring particularly into the general history of the patient he changed his diagnosis to that of spinal arthropathy. The latter was reasonably confirmed by the co-existence of certain ataxic symptoms. These were not so marked in connection with the tendo-reflex as with the co-ordinating muscular power in the extremities, which was associated with a disease of the articular ends of the bone, due to a faulty nutrition, and dependent on central nervous lesions. The conclusion was at first forced upon him rather by excluding apparently similar local conditions from consideration (principally among these being that of osteo-arthritis) than by many of the more usual and positive symptoms associated with locomotor ataxia. Since this case had been under observation, however, the diagnosis had been confirmed not only by the progress of the local lesions, but by the development of marked tabetic symptoms. The joint itself had progressively degenerated, its articular extremities had worn away, become more expanded and unshapely, the ligaments had degenerated, and as a consequence luxations were produced by the slightest efforts on the part of the patient, rendering the extremity absolutely useless for purposes of locomotion.

A point in the diagnosis was that these changes had been going on symmetrically, there having been no nodosities developed, as is the rule in osteo-arthritis.

Pathologically, spinal arthropathy was in every essential particular different from purely arthritic degeneration. In the former the bone tissue was first affected by direct interference with its nutrition through the vaso-motor system; the destruction of the cartilages and synovial membranes, and the gradual absorption of osseous elements being secondary manifestations of the disease. In osteo-arthritis the processes were reversed, the soft tissues in and around the joint being the first to be attacked, and undergoing inflammatory rather than trophic changes. The general or ataxic symptoms were not so marked in connection with the absence of reflexes as with lack of the co-ordinating power in the extremities and in the eyes.

The left eye particularly showed marked disturbances of nerve influences, principaly as affecting the third pair of nerves, there being ptosis, divergent strabismus, and consequent diplopia. The latter symptoms had been, during the past year, slowly but markedly progressive. The other joints in the body were free.

This, then, was the case in brief. The disease of which it was an example was either very rare, or not recognized as often as it should be. He had seen but one other. Very many of his professional friends, of large experience, had not seen as many. In the other case to which he referred, which, like this one, was a hospital patient, the disease was also confined to the knee, both joints being nearly similarly affected, and associated with more pronounced ataxic symptoms, especially such as referred to the eye complications—ptosis, strabismus, and diplopia.

In both there was a history of specific infection, and in both the usual treatment for the same resulted negatively. The same might be said of medication generally in regard to these cases; the local lesions progress despite everything that had been tried to arrest them, and we were seemingly narrowed down to the simple expedient of giving support to the parts and thus reducing friction and pressure to the minimum.

DR. A. A. SMITH then read a paper (see p. 178) entitled

SOME CONSIDERATIONS ON THE DIAGNOSIS AND PROGNOSIS OF ABDOMINAL ANEURISM.

DR. W. M. POLK said he had had no practical experience which differed from that mentioned by Dr. Smith; in fact, he was obliged to go back seven years to recall any case of abdominal aneurism. They are not common, and the Society was fortunate in having the opportunity of hearing the three cases presented by Dr. Smith. But there was one thing which was a subject of congratulation for those gentlemen who had to deal with intra-peritoneal developments, and that is the prompt tendency which the peritoneum exhibits to resist the progress of any of these formations by throwing out plastic exudation. He should think that in case of aneurism this was a condition which might go on, perhaps not so rapidly as where the inflammation is more acute, but still might develop a membrane which would prove decidedly conservative in its influence upon the growth.

As bearing on the protective character of peritoneal adhesions he could recall an operation that illustrated what surgeons might be willing to do. It was a case of vaginal hysterectomy, and after removal of the uterus he did not close the opening, but simply stuffed it, after withdrawal of the uterus, with iodoform gauze, putting it in direct contact with the peritoneal surfaces, with the confident expectation that the excavation left would be closed over within forty-eight hours, and in that manner exclude percolations of any material which might not be absorbed by the gauze. He expected that the newly-formed exudation would stand guard between the abdominal cavity and the vagina. In the absence of septic influences he thought we might rely upon the peritoneum doing that very thing.

DR. H. F. WALKER gave condensed histories of two cases of abdominal aneurism which came under his care while he was visiting physician to Bellevue Hospital.

In the first case, the nature of the disease was recognized. In the second, there was such obscurity of symptoms, and such absence of the crucial signs of aneurism, that though that disease was daily in mind in the examination of the patient, the diagnosis was only made at the autopsy.

Patient number one, admitted July 12, 1875, was a man of forty, a laborer, whose previous health had been good. Nine months before, while driving, he had lost control of his horses, was thrown from the wagon, and struck his left side, in the lumbar region, against a lamp-

post. Six months after, a small tumor appeared, which since then has gradually enlarged. Its appearance and growth have been attended with dull and shooting pains.

The tumor, at time of admission, had its centre four inches to the left of the median line, one and a half inch above the crest of the ilium. It was seven inches in vertical, and seven and a half inches in transverse diameter. As the patient lay supine, its highest point was raised one and a half inch above the general surface. It pulsated with the radial pulse, but no bruit could be heard by careful auscultation, though ten days after admission an aneurismal bruit was detected. One month after entrance the tumor had greatly increased, especially in the transverse and antero-posterior measurements. These were, respectively, eleven inches transversely, and two and a half inches above the surface. The vertical diameter was seven and a half inches. The tumor continued to grow till September 3d, when the last measurements were made: vertical diameter, thirteen inches; transverse, fifteen inches; height of the tumor above the surface, six inches.

September 5th the patient died of asthenia, worn out by long-continued pain and inability to assimilate food.

The treatment had been the maintenance of the supine posture, and opium for relief of pain.

The autopsy was made September 6th, under supervision of the curator.

The abdominal cavity, left side, was occupied by a tumor which dislocated the kidney and the intestines. On its anterior or ventral surface lay the psoas muscle much flattened; on the lateral surface the first, second, third, and fourth lumbar vertebræ were much eroded, the intravertebral cartilages preserving their size and shape. The last rib also was eroded. Posteriorly, the tumor was covered by skin, lumbar fascia, and muscles. Its capacity was estimated at one and a half gallon. A probe passed from the heart through the descending aorta entered the sac near the origin of the cœliac axis. From below upward, along the external iliac artery, the tumor was entered between the mesenteric arteries. Between these two points, a space of about two inches, the coats of the artery exist. Between these points a sacculus extends across the spinal column, and presses against the transverse fissure of the liver. Its capacity is six ounces. It is formed of the arterial coats. A probe pressed against the posterior or lateral inner surfaces of the larger sac is not perceptible to finger outside. The tumor, on opening, is found filled with laminated fibrin and clots, making the solid thickness of the tumor, posteriorly, to be from six to eight inches. The coats of the artery cannot be recognized in this region, the sac here being formed of fascia and skin.

The growth of the tumor has been backward between the psoas muscle and vertebræ. Anteriorly, the sac of the tumor is formed of the thickened peritoneum. Liver flattened and compressed. Kidneys: both show chronic diffuse nephritis, and are studded with emboli. The left is compressed; there are clots in the renal arteries. Coats of the aorta atheromatous. Heart normal.

The second case is that of a woman, aged thirty-two, who was admitted to Bellevue Hospital October 3, 1882. She was anæmic in appearance, even phthisical. For three years she had been an opium-eater. For six months she had had chronic diarrhœa. To gain relief from this, and pain located in the back, running up to the spine of the scapula, she came for treatment. This pain was described as originating in the region of the liver, which was enlarged.

October 13th.—The diarrhœa is relieved, but the pain in the back is greater and attended with dyspnœa. Examination shows flatness, with loss of respiratory murmur and voice-sounds, over the right lung up to the ninth rib, and over the left to an inch above the angle of the scapula. The hypodermic needle introduced brought a small amount of blood-stained serum from the right side, and clear serum from the left. The heart gives a singular variety of murmurs.

[These in their variations were probably all from the aneurism, and none from the heart. Their character changed from time to time.]

The whole left side of the chest receives a forcible heart impulse. A loud systolic murmur, musical in character, is heard at apex, transmitted to the left. The apex impulse is an inch outside, and just above the nipple. A thrill is felt over the pericardium, and over the whole of the pericardial space a friction sound is heard, increased by the patient's bending forward, and not interrupted by her holding the breath.

October 28th.—The fluid is almost gone from the left side. The liver is now much enlarged, its increase in size having been gradual since the patient's admission to hospital. In the mammary line it extends nine and one-half inches, its lower border to an inch below the umbilicus. Posteriorly and in the lateral right hypochondriac region it gives a half-elastic, half-boggy sensation to the hand, as far down almost as the iliac crest.

[Because of this sensation, and because the patient had had diarrhœa of chronic character, the small needle of the aspirator was introduced into the side at several points in right side, in the hope of finding the pus of a hepatic abscess. This was done on several occasions, withdrawing only a trifling amount of blood and without subsequent attendant symptoms. A possible fecal accumulation was eliminated by tentative treatment also.]

November 3d.—The note in the history is that the pulse of radial carotid and femoral arteries is synchronous.

November 7th.—Friction-sounds over heart. Loud systolic murmur; its greatest intensity at the third intercostal space at the left of the sternum, transmitted toward the right. Diminished area of dulness over the liver. This diminution has been constant and gradual since the 3d instant.

November 12th.—A double murmur is now heard along the eighth rib, one and one-half inch each side of the sternum.

November 24th.—A swelling, the size of an egg, found in the back, on right side, at level of tenth rib, obscurely fluctuating. It gives to the hand the emphysematous crackle. The hypodermic needle draws only blood. The patient died this day. The autopsy was made by Dr. Welch, the curator:

"All the thoracic organs are pushed upward. The connective tissue over the pericardium emphysematous. Pericardium contains two ounces of fluid, but no evidences of recent pericarditis. Heart not hypertrophied; no fatty degeneration. Its valves competent, and there is no atheroma of thoracic aorta. Left pleura contains twelve ounces of fluid. The left lung somewhat compressed; the right, pressed upward, was carnified in the lower lobe and contained no air.

"Liver is six inches below the free border of the ribs in the mammary line. The pushing forward of the liver and the arching of the diaphragm gave the impression of great enlargement of the liver. The viscus is much thinner than normal, and a tumor lies behind it, to which it is adherent. The spleen is pressed to the left. The stomach is pressed upward and forward, the intestines downward; the right kidney compressed by, and adherent to, the tumor, the left normal. The aneurism is in the abdominal cavity, just below the diaphragm. Its size is twice that of a normal liver. The aorta enters the superior surface of the tumor just beneath the diaphragm, and issues from it at the level of the first lumbar vertebra. The tumor lies on each side of the vertebral column. Its anterior wall is made up of the coats of the distended artery, connective tissue to which adjacent organs are adherent, and of laminated fibrin. Its posterior wall is formed of the vertebral column, ribs, intercostal muscles, muscles of abdominal walls, and by a layer of laminated fibrin about *five inches*

thick. The abdominal aorta passed along the anterior wall of the tumor, the vena cava lying alongside and not compressed. Just below the diaphragm, half an inch above the cœliac axis, was an opening into the tumor on the posterior wall of the aorta one-half inch wide, two inches long. The wall of the aorta was clearly seen to spread out and be continuous with the wall of the aneurism. This tumor was hard, lined with laminated fibrin, four inches thick posteriorly. It contained ten ounces of clotted blood.

"The bodies of the eighth to the twelfth dorsal vertebræ, inclusive, were eroded. The cartilages were intact. The eighth, ninth, and tenth ribs on the right side were carious—the tenth being entirely separated from the vertebra. Over this point the external swelling which gave the emphysematous crackle had formed."

Dr. E. Darwin Hudson, Jr., remarked, with reference to Dr. Walker's observation concerning the escape of the intervertebral cartilages, that it was also the rule in thoracic aneurism that the costal cartilages remained unaffected while the ribs were absorbed. It is a singular fact, but he thought it of quite common occurrence, and attention had been directed to it by Hayden, and others.

Dr. Kinnicutt thought it could be quite confidently asserted that abdominal aneurism was of longer duration as regarded the life of the patient than thoracic aneurism, a fact which could be accounted for otherwise than by the protection afforded by peritoneal thickening. Such, at least, had been his experience.

Dr. Smith said the point which he wished especially to develop in his paper was the protective thickening of serous coverings in either thoracic or abdominal aneurism. He thought the very fact that it is protective in many cases might make the prognosis unfavorable in other cases; for, if the peritoneal covering is so thick as to protect the sac in one portion, it might allow the sac to dilate more readily at other points, and thus allow it to rupture more quickly unless protected in that particular region also.

In none of his cases was there any evidence of syphilis, and it might be that traumatic aneurism progressed more slowly, and the cases were more prolonged than those which occur with the degenerative changes affecting the blood-vessels due to the specific disease.

Dr. Walker said it seemed to him that thickening of the walls of the aneurism was more likely to be from internal deposit than from thickening of the peritoneum.

Dr. Smith said his paper did not refer to thickening of the inner surface of the aneurism, but simply to those cases which were protected by outside influences.

Dr. Polk asked Dr. Smith if he had any information touching the protective influence on abdominal aneurism exerted by the pressure of other abdominal tumors.

Dr. Smith replied that he had not.

Dr. Polk said the reason he asked the question was because Dr. Gillette recently reported an extremely interesting case of this kind. A woman about thirty years of age had a distinct abdominal aneurism. She became pregnant, and he was seized with the usual anxiety under those circumstances; but as the woman seemed to be getting along very well he allowed the case to progress without interference, and she finally went to term, suffering no inconvenience during her pregnancy, and passed through labor without accident. The result upon the abdominal aneurism was a marked diminution in its size and a marked amelioration of the symptoms, all of which Dr. Gillette attributed to the influence of the outside pressure brought to bear upon the aneurism, very much in the same way as pressure in Dr. Smith's cases from thickening of the peritoneum, although in an entirely different manner, and not so direct.

Dr. J. B. Hunter, as bearing somewhat upon this question, said he would mention the dense covering found in some cases of abscess. He had seen accumulations of pus in the peritoneum which had been there for years probably, and the sac was composed entirely of thickened peritoneum.

Dr. Smith remarked that he did not believe the condition which he had described would account for the long duration of the disease in some cases of abdominal aneurism.

The President queried whether iodide of potassium, the favorite remedy in the treatment of aneurism, exerted any effect in producing this protective influence.

Dr. Smith said that in his two cases there was an injury, and probably the first step of the process was an attack of peritonitis, localized, and the result of the blow. In the case of the woman now under observation there was no history of traumatism at all. The thickening is simply the result of repeated attacks of inflammation.

Infectiousness of Secretions in Purulent Catarrhal Inflammation of the Ear, Eye, and Nose.

Dr. Samuel Sexton said that a considerable number of children under six or seven years of age, especially those attending the public schools, came to his aural clinic at the New York Eye and Ear Infirmary with catarrhal inflammation of the upper air-tract, in which the ears, eyes, and nose were particularly affected, there often being purulent discharge from these organs. The cutaneous surfaces adjacent were frequently found to be the seat of dermatitis, or even of an eczematous eruption, due in part to the irritation of secretions. The dental irritation of this period was often found to be active, and in the run-down, cachectic children of the poor—usually but illy provided for in respect to food and clothing—catarrh of the head is of extremely frequent occurrence. These patients are often sent from one department of the Infirmary to another to receive treatment for the ears, eyes, and nose, and where there is also eczema of skin the distress is greatly increased.

Dr. Sexton asked what the views of members of the Society were in regard to the causation in this trouble; he himself has considered that it was due to the causes mentioned, which are of such general prevalence among the class of children in question, whether attending school or living in institutions, where, like the schools, there was overcrowding, and where hygiene was defective, rather than to contagion or the infectiousness of the purulent matter secreted; at least this seemed to be the case as far as the ears and nose were concerned. He was not informed as to why purulent secretions from the eye, however, were more infectious as regards that organ itself than those from the ear and nose, and would be glad to learn the theories offered in explanation.

Dr. E. G. Loring thought that any secretion from the eye which was purulent was contagious. It was a most remarkable fact that secretions from the ear were not contagious to the eye. Children with otitis media never get ophthalmia, so far as he knew, from becoming inoculated with the discharges from the ear. Probably there is some general condition of the system which favors this contagion.

Iron or Potassa?—Dr. John W. Taylor, of Crawfordsville, Ind., writes: "In The Medical Record of January 9th I notice a communication from Dr. Tipton, which provokes from me the above query. The Doctor ascribes all the curative virtue in the prescription to the iron alone, and leaves the potash and the glycerine out in the cold. Is this fair? Did not Seligmüller achieve the like brilliant results with the saturated solution of chloride of potash alone? If that drug was so efficacious in his hands, is it not possible that it is the curative agent in the prescription given by Dr. Tipton? I think it more than probable. For several years I have used Seligmüller's method exclusively, and have been so well satisfied with its work that I have come to rely upon it with the greatest confidence in every case in which there is sufficient vitality to respond to any treatment."

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 4, 1886.

A. JACOBI, M.D., PRESIDENT, IN THE CHAIR.

DR. B. F. SHERMAN, of Ogdensburg, was introduced by the President.

DR. M. ALLEN STARR read a paper (see p. 174) on

THE INTRA-CEREBRAL TRACTS,

their physiology, and its bearing upon the diagnosis of lesions of the centrum semiovale.

DR. SHERMAN inquired of Dr. Starr whether physiologists had demonstrated what might be called a thermal centre, to which Dr. Starr replied by mention of the investigations in that direction by Eulenberg and others.

PERMANENT DRAINAGE IN ASCITES.

DR. AUG. G. CAILLÉ related the histories of two cases, and made them the basis of some remarks. About four years ago he saw an elderly gentleman suffering from cirrhosis of the liver, in whom the symptoms depending upon ascites were so marked as to urgently demand tapping and repetition of the operation. He was tapped nine times in the course of seven months, a pailful of serum being removed each time. Before the tenth operation Dr. Caillé determined to attempt permanent drainage, although the danger of exciting a peritonitis or other serious complication was fully appreciated. An incision an inch in length was made in the median line, half-way between the umbilicus and symphysis pubis, a trocar and cannula introduced, the trocar withdrawn and a rubber tube inserted. After withdrawl of the fluid the tube was allowed to remain, iodoform being put upon the dressing at the mouth of the tube, and the fluid allowed to drain and be absorbed by towels. Some eczema developed under the dressing, which disappeared under appropriate treatment.

After drainage had been established the œdema disappeared rapidly, the heart-action improved, the breathing was freer, the troublesome cough disappeared, the bowels became regular, the appetite improved, and the patient became able to go about, wearing all the while the tube. The rubber cannula remained *in situ* about nine weeks, when it was removed, and at the end of another four weeks the opening closed. The patient was able to be about his duties nine months, there being no return of the œdema nor of the ascites. After nine months his strength began to fail, and he finally died of heart-failure. Two weeks before death there was a return of slight œdema of the ankles. At the autopsy were found cirrhosis of the liver and fatty heart. Careful inspection of the peritoneum at the seat of puncture revealed no evidence of inflammation.

The second case was similar, and in addition there was marked purpura hemorrhagica, epistaxis, bleeding gums. The patient had no appetite and was unable to sleep. He was treated as was the other patient, in this case a rubber tube being employed to conduct the drainings from the rubber cannula to a bucket by the bed containing a carbolic solution. The tube was worn for seven weeks; the ascites and œdema disappeared; the appetite improved; there was, in short, improvement in all the symptoms. The patient was able to pass ten weeks with his family in the Catskills, and continued to live a comfortable existence until the spring of 1885, when he died suddenly, as was supposed of heart-failure, when attempting to get out of bed. There was no return of the ascites. An autopsy was not allowed.

In his general remarks Dr. Caillé considered four questions: First, what are the symptoms and dangerous mechanical effects of ascites? Second, how is the collateral circulation established in cirrhosis of the liver? Third, will the absence of intra-abdominal pressure, or pressure from ascites, promote collateral circulation and functional activity of important organs, and thereby prolong life and add to the comfort of the patient? Fourth, how is drainage best accomplished?

After considering these questions the author said he was inclined to believe, from this limited experience, that we need not fear peritonitis so much when ascites is present as under other circumstances. Too much importance, however, should not be attached to these two cases, for the number was too small to judge of the value of this procedure. It was his opinion, however, that it should be given a trial in cases of ascites which required two or more tappings for reaccumulation of fluid.

THE PRESIDENT said it appeared to him that Dr. Caillé had done in these two cases what might have occurred spontaneously. Probably some of the gentlemen present had seen cases of extreme ascites in which spontaneous rupture of the abdominal walls had taken place. He had seen some such cases. The place of rupture was usually in the median line, particularly at the umbilicus. In such cases there was, of course, a permanent fistula established, and instead of allowing it to occur at a spot which was not convenient or pleasant he thought it was better for the surgeon to make the opening where he wished it should be established. There was such a case in the German Hospital the past year, that of a heavy German, in whom spontaneous rupture took place at the umbilicus, allowing of the escape of the ascitic fluid. It healed and reopened several times in the course of a few months. The patient felt so well satisfied with his condition that he left the hospital, but naturally the shrinking liver and swelling spleen still remained.

The President then described a case of encysted ascitic fluid which occurred in his ward in the Bellevue Hospital last year, in which the physical signs were almost exactly those seen in a patient over twenty years ago. In the case seen long ago he made the diagnosis of ovarian tumor, and although post-mortem examination proved his error, he still thought that the diagnosis of ovarian cyst was the only one justified by the signs during life. He had this case in mind when contemplating an operation upon the patient in Bellevue Hospital, yet the signs were so plainly those of an ovarian cyst that an incision was made, when it was found that the fluid was ascitic, limited by adhesions. Permanent drainage was then established for a time, and the patient improved and left the hospital. He had since heard that the fluid had reaccumulated. There was a family history of tuberculosis, and it was probable she had tubercular peritonitis.

After hearing of the operation for permanent drainage in ascites by Dr. Caillé, the President had resorted to it in one case of cirrhosis of the liver in which there were signs of small liver, enlarged spleen, purpura, epistaxis, increasing dyspnœa, etc. The ascitic fluid was drained away through a tube passing between the patient's legs to a bucket. After a time the end of the rubber cannula was closed at night with wax. The patient was much relieved, but, as in all cases of advanced cirrhosis, death must finally ensue, and in this case the patient died of exhaustion not long after drainage had been established. The autopsy revealed no peritonitis. He was convinced that Dr. Caillé's operation was a good one.

DR. GARRIGUES asked a question with regard to the working of a drainage-tube and band exhibited, and DR. MEYER related a case which he thought went to show that permanent drainage might be established when the fluid in the peritoneal cavity contained pus, and that possibly the drainage might be made to take place through the vagina.

DR. LINDLEY raised the question of the medicinal treatment of cirrhosis of the liver, and said that among the Dutch in South Africa a popular remedy was hone taken daily. It might appear absurd, but he said he had tapped a man with ascitic fluid, and an old woman told him to give honey. The patient took a pint of fluid honey daily, and had no further trouble.

Dr. Sherman suggested that some medicinal property of the flowers from which the honey was made might have had the curative effect.

The President said that during the first part of his professional career he was opposed to the use of mercury except for syphilis. But during the past ten or twelve years he had gotten over that prejudice, and he was satisfied that corrosive sublimate given in small doses for a long period of time had a beneficial effect upon interstitial inflammations, whether they occurred as a cerebritis, a nephritis, a hepatitis, etc. He felt sure that it had stopped the progress of interstitial changes in a number of cases; and in patients in whom the disease had affected only a part of a vital organ this drug had the power of checking the progress of the disease and thus of prolonging life indefinitely.

The Academy then adjourned.

Correspondence.

OUR LONDON LETTER.

THE SOCIETIES—INCREASE OF WHITE BLOOD-CORPUSCLES IN INFLAMMATION—SUCCESSFUL REMOVAL OF A TUMOR FROM ROOTS OF LAST CERVICAL AND FIRST DORSAL NERVES—PROSTATIC CASTS—SIR WILLIAM DALBY—THE LONDON TEACHERS AND THE CONJOINT SCHEME—THE NEW M.D.—MR. HUTCHINSON'S LECTURES AT THE MEDICAL SOCIETY OF LONDON—SECONDARY AND TERTIARY STAGES OF SYPHILIS—THE ANTIDOTAL POWER OF MERCURY—THE COLLEGE OF PHYSICIANS AND ST. AUGUSTINE—DR. HEYWOOD SMITH AND THE ARMSTRONG CASE.

The societies have now resumed work since the Christmas vacation. The general character of their proceedings during the last week may be described as somewhat dry, but a few communications were of some interest.

The most noteworthy feature of the last meeting of the Royal Medical and Chirurgical Society was the reading of an elaborate paper "On the Increase in Number of White Corpuscles in the Blood in Inflammation." The paper was based upon numerous and laborious observations made on nearly twenty cases by the author, Mr. T. P. Gostling. The cases included examples of iliac abscess, pelvic cellulitis, empyemas, phthisis, typhoid, acute rheumatism, etc. The author concluded that white corpuscles are increased in number in suppurative inflammations, especially when accompanied by tension, the normal proportion (1 white to 333 red corpuscles) being doubled in many cases; that they are slightly increased in parenchymatous inflammations; and that they are not increased in inflammations accompanied by serous or sero-fibrinous exudation.

After the reading of Mr. Gostling's paper a short discussion took place, mainly as to the source of the additional white corpuscles. Some of the speakers thought they were due to reabsorption of white blood-corpuscles. A little sparring here took place between Dr. Money and Mr. Horsley, the former of whom maintained, and the latter denied, that white corpuscles might be absorbed by the lymphatics. The former is a young physician, and the latter now on the surgical staff of University College Hospital, in which institution they were formerly fellow-students.

The next paper was by Dr. Mitchell Bruce and Mr. Edward Bellamy, and was on a case in which a tumor growing from the roots of the last cervical and first dorsal nerves had been successfully removed. The operation was undertaken in consequence of the growth having caused acute pain and eventually complete paralysis of the arm. Some of the cords of the brachial plexus were found to be frayed out over the tumor, which was sarcomatous in nature. The former acute pain ceased immediately after the operation, but paralysis remained, though this also finally disappeared after persistent use of the constant current. The patient died from hemiplegia more than a year afterward.

At the Clinical Society Sir Andrew Clark related a unique case of acute prostatitis which had been seen by Sir James Paget and himself. During the whole course of the case the urine was found to contain hyaline cylinders and small flask-shaped hyaline masses, which were in some cases connected with the cylinders. The casts were of the same character as those found in the urine in cases of acute nephritis or acute congestion. An important diagnostic point was the presence of flask-like bodies attached to the hyaline cylinders. He regarded these as being probably moulds of the follicles of the prostate. The presence of prostatic trouble, and the fact that the urine was healthy, *plus* a little albumen, were the other conditions favoring the diagnosis of the prostatic origin of the hyaline casts. He had met with two other cases, which were similar but less acute. Sir Andrew Clark's communication evoked a good deal of interest. Professor Greenfield, of Edinburgh, referred to four cases he had met with, in which the urine contained concretions having some of the characters of corpora amylacea. Sir Andrew Clark remarked that in the urine of women he had always found starch-like bodies, and suggested that they might be due to their use of violet powder in the toilet. Urinary chemistry and microscopy, therefore, still abound in pitfalls for the unwary despite many advances. It is not very long since a hospital surgeon made a short communication to one of the medical journals, in which he narrated an experience he had just had. On examining some urine sent to him for the purpose he found some yellow crystals, which at first he supposed to be cystine. After about two hours' work he discovered them to consist of iodoform, and subsequently discovered that the patient's bladder had been recently washed out with a lotion containing some iodoform. The administration of drugs by the mouth is also likely in some cases to lead to difficulties in urinary analysis.

The shower of knighthoods to the profession continues in a somewhat inexplicable manner. Odd reasons have been suggested as to the *raison d'être* of some of them. Had, for instance, the conversion of Dr. James Sawyer, of Birmingham, into Sir James Sawyer, anything to do with Lord Randolph Churchill's recent candidature in that town? The latest medical knight is Mr. Dalby, Aural Surgeon to St. George's Hospital. Mr. —I beg his pardon—Sir William Dalby has produced a very fair book on aural surgery and has actively promoted the oral method of teaching deaf-mutes. I do not know what other claims he has to the distinction just conferred upon him, further than his possessing sufficient money to purchase the practice and house of the late Mr. James Hinton, and keep up the style of a West End fashionable specialist.

The London teachers are in arms against the Conjoint Board, or rather against the severity of its examiners. It is declared that last July eighty per cent. of the students were rejected, that a considerable number of these were really well up, and that a few very ignorant men got through, while in one case a certificate was actually sent to one candidate who never presented himself at all for the examination. In October the standard was dropped somewhat, but not enough, and in the examination now just concluded it has been still further lowered. The questions set by the examiners have been closely scrutinized by the authorities of the two colleges before being accepted. Moreover, meetings of teachers have been held with a view of censuring the conduct of the colleges, and the latter have appointed persons to re-examine the regulations, with a view of bringing them into harmony with the teaching of the schools. I am informed, on the highest authority, that the earlier examinations are likely to be completely remodelled, a majority of the Committee being fully decided to report in favor of such a

thorough change. I understand that the two colleges are fully resolved to follow up the subject of obtaining powers to grant the M.D. degree. Some doubts were felt at one time as to whether the College of Physicians would heartily co-operate, but these are now removed, and I now learn that the College is prepared, should the proposed Royal College of Medicine be formed, to appoint scholars from its own ranks to conduct the Arts examinations for the degree in medicine. This affords an ample guarantee that sufficient academic training will be exacted from the new graduates, as among the fellows and members of the College are many distinguished classical scholars.

The burden of Mr. Hutchinson's second lecture (Lettsomian Lectures "On some Moot Points in the Natural History of Syphilis") was the relationship between secondary and tertiary phenomena. He protested vigorously against the older doctrines that there was an essential difference between them, and that certain forms of disease could be named "secondary" and others "tertiary." Thus it had been considered that visceral lesions, gummata, deep ulceration, and periostitis were characteristic tertiary phenomena. But cases had been met with in which these affections had occurred very early. Mr. Hutchinson cited two in illustration. One was that of a young man aged twenty-one, who was admitted into the London Hospital with the remains of a hard chancre on him, being also covered all over with a papular eruption which was ulcerating in places. He died suddenly, and gummata were found in the testicles, spleen, and heart. Death had been caused by the softening and ulceration of the cardiac gummata. According to the patient, infection had occurred only four months previous to admission into the hospital. Another case was that of a young man, not fairly over the secondary stage of syphilis, who also died of diffuse gumma of the heart. Large visceral gummata, said the lecturer, were common in syphilitic infants who still had secondary eruption present. In adults, it was an everyday occurrence to observe symptoms implying periostitis, transitory nervous affections, or even visceral affections, during the secondary period. Such cases had been explained on the supposition that the disease had run an unusually rapid course. Mr. Hutchinson, however, repudiated this plea, and boldly claimed that there was no lesion whatever which might not happen, and no tissue which might not be attacked, during the secondary period. It was impossible to classify the symptoms as secondary or tertiary according to the tissues attacked. These terms should rather be used as applicable to distinct periods of time. With reference to the early occurrence of so-called tertiary symptoms, the lecturer remarked that the gummata of the early period were small and numerous, while those of the later one were large, and often few, or even single. Those of the early period easily disappeared, either spontaneously or under mild treatment, while those of the tertiary stage persisted and grew indefinitely, unless adequately treated. Speaking generally, it was still true that visceral affections, etc., belonged to the tertiary stage, but this was not constant.

Many things were omitted in the tertiary stage which were common in the secondary, but there were few tertiary conditions which did not find their representatives in the preceding stage. This, said Mr. Hutchinson, favored the view that tertiary symptoms were often relapses, so to say, of the secondary ones. There was a recrudescence of morbid tissue in tissues which had been damaged at a former period. Everything that was tertiary was local in a sense not true of any of the secondary lesions. Thus the tendency to symmetry diminished as time went on, and, except certain nervous maladies, concerning which there was much debate whether they were syphilitic or not, we might say that nothing in the tertiary stage was ever bilateral except by accident.

For clinical convenience, we might recognize an intermediate period during which, in many patients, there was an absolute abeyance of all symptoms. If symptoms should occur after a prolonged period of immunity, they were always definitely of the tertiary class, and almost invariably non-symmetrical, and, if on the external parts, remarkably amenable to local treatment only. As an illustration of this, Mr. Hutchinson cited palmar psoriasis occurring in the tertiary stage. This affected one hand only, and usually that which the patient used most in his occupation; there was usually a single patch of some size, and the condition often yielded readily to the local application of mercurials or of iodoform. The hand often suffered from psoriasis in the secondary stage, but then both palms were affected, and there were usually in each a number of separate circular patches. Such symmetrical and multiple patches were obviously due to blood-infection.

For convenience, we might say arbitrarily that the secondary stage ended with the second year, and that about this period the disease ceased to be capable of spreading by contagion, or of being transmitted to offspring. In many patients the secondary stage (thus defined) ended with the first year, while in a few it lasted beyond the second year. In many persons the stage intermediate between the secondary and tertiary stages was not one of immunity, but was occupied by conditions partaking of the characters of both stages.

Mr. Hutchinson then proceeded to discuss the influence of mercury. He has for many years been a strong advocate of mercurial preparations *given for some time in small doses*. His rule of practice, he said, has been to give a single grain of gray powder from three to six times daily, according to circumstances, and seldom for a shorter course than six months in the first instance. He considers that mercury possesses a true antidotal power. If it were stopped, in many cases a very remarkable proof of its antidotal efficacy would occur. An outbreak of symptoms would often occur within a few weeks of its suspension, showing that it was the mercury which had held the poison in check. Mr. Hutchinson asserted that he had never, in any single case of late years, seen a severe eruption on the skin develop itself after a mercurial course of the kind indicated had been begun. It manifested antidotal power, therefore, in that it could not only remove, but actually prevent, the most conspicuous manifestations of the disease. He could not make so strong an assertion as to some of the symptoms of the latter part of the secondary stage, for he had seen iritis and neuro-retinitis occur occasionally, and even with severity, in cases which had been well treated, and, in exceptional cases, he had observed disease of the arteries of the brain. In, however, a large majority of cases a course of small doses continued, as indicated, for half a year was sufficient for the complete and permanent cure of the disease. No relapses occur and the patients remain afterward in excellent health.

The examination for the membership of the College of Physicians, which began a few days ago, and is now in progress, has afforded the authorities of that body an opportunity of having another fling at Dr. Heywood Smith. The President and Censors examine for the M.R.C.P. In addition to an examination in medicine (written and practical), a certain amount of linguistic knowledge is required. For this purpose extracts from Latin and Greek authors (and of late years French and German ones also) are given for translation. These are mostly taken from ancient medical writers on medicine, but on this present occasion the classical scholars of the college have exercised their ingenuity, and have unearthed a passage from St. Augustine in which the wickedness and impropriety of making examinations of young girls is denounced. Readers of the passage will no doubt take its introduction into the examination paper as a hit at Dr. Heywood Smith, and such it is doubtless intended to be. Such an indirect shot is no doubt ingenious, but scarcely generous while the recipient is still smarting under the public reprimand lately administered to him by the Presi-

dent of the college (Sir Wm. Jenner) in the presence of the assembled Fellows. This was for Dr. Heywood Smith's conduct in reference to the now notorious Armstrong case. In a series of sensational articles, the editor of the *Pall Mall Gazette* (Mr. Stead) had asserted that girls (virgins) could be openly purchased for immoral purposes, and followed up this general assertion by narrating in detail the history of "Lily" Armstrong, who, he said, had been sold by her mother for immoral purposes. It subsequently transpired that Mr. Stead's agents had deceived him, and that the mother had been induced to part with her child under false pretences. Mr. Stead took the child to a midwife for examination as to virginity, and subsequently to a brothel, where he remained some time with her, though for what purpose does not appear, except probably to manufacture material for some more sensational paragraphs. From thence the child was taken to Dr. Heywood Smith's house, where she was again examined (this time under chloroform) by Dr. Heywood Smith, at Mr. Stead's request, with the object, avowedly, of protecting the latter against any charge which might be subsequently brought against him. For examining the girl under these circumstances Dr. Heywood Smith has been severely censured, both by the judge in the recent trial and by the President of his college. It certainly seems unjust and ungenerous to add indirect censures to those he has publicly received. He is widely known as a high-minded Christian physician, and no one doubts that, however imprudently he may have acted, his motives for his conduct in the Armstrong case were at any rate good. I wish all his detractors may be conscientiously able to say as much of their own.

WOMEN AND BEES.

To the Editors of The Medical Record.

SIR: A correspondent, in your issue of January 16th, p. 81, writes as follows: "If we go to the bee for information we find that the same egg, according to its environment, will develop into a neuter gender, the worker; or a fully developed female, the queen bee; or into a more highly developed being, the male or drone." It is to be regretted that your correspondent did not speak sooner, so that our text-books of physiology might have been differently compiled. "Herman's Handbuch," for one, need not then have been so radically wrong. In vol. vi., part 2d, p. 161, of this work, Hensen tells us that among bees unimpregnated eggs are those that produce males. The young queen who has never been fructified, and the old queen whose spermatic receptacle is empty, both produce broods consisting of drones only. We are told, further, that this result, humanly so desirable, is considered a disaster in the bee community, and that efforts to rear a queen by changed environment of the immature drone is then persistently but ineffectually made. Seibold also thought that he had observed that the ova which developed into drones contained no spermatozoa, while in those which developed into females spermatozoa were found. The reason why the impregnated female ever produced drones was, in his opinion, owing to the greater size of the drone's cell, which permitted the entrance of her ovipositor without compression of the abdomen. Into the other cells, on the contrary, she entered with difficulty, and by purely mechanical action semen would be expressed from its receptacle and impregnation occur.

Until the advent of your correspondent, among the bees, at least, the female was not considered an undeveloped drone. Whether her constitution were thereby dwarfed or complicated, she was the product of the egg capable of producing the drone, plus elements from without. The occurrence of hermaphrodite individuals among bees was even supposed to strengthen this view, and it was said that in this case the male development had already commenced before impregnation occurred, and hence its tendency could not be completely changed.

Another point in this connection is also somewhat new. Your editorial of December 2d credits Mr. Terry with saying that the existing and increasing excess of females over males in all the fully settled portions of the country is due to a gradual decline in the strength of the mothers. Quoting again from Hensen: In Europe, out of 5,900,000 births, boys were born in the proportion of 106 to 100 girls; and even during the past year, in this city, there were born 15,534 boys to 14,503 girls, or boys in the proportion of 107 to 100 girls. Evidently Mr. Terry does not live in New York. As you tell us that he has statistics to prove his point, it follows that there is a part of the country where girls are being produced in excess. To the future physiologist this will be an interesting fact.

The proposition that in the case of physical debility in the wife female children result, is another remarkable statement. By coupling this with the statement that the more sickly the wife the more debilitated the children, female and debilitated are made synonymous terms, and yet in a previous paragraph it has been already statistically proven that girls are comparatively hardy, while boys die of debility and marasmus at an excessive rate. Hensen is deficient in this matter also. He makes no mention of woman's increasing weakness as a cause of this disproportionate mortality of baby boys. Apparently he was misled by finding the same tendency among animals, such as the sheep, the dove, and notably among frogs. The brief life of the male insect also possibly had its influence.

Hensen says (p. 208) males predominate where the ova have less vital force. Spermatozoa antagonize this condition; they make the egg "entwickelungsfähiger," and increase the number of females. He says further (p. 168), impregnation has no part in the generation of the embryo. The spermatic bodies but assist or modify its development, and all are familiar with the fact that segmentation occurs in the sterile as well as in the impregnated egg.

Dr. Heitzman has suggested that where the male is developed more spermatozoa penetrate the ovule, and that where the female is developed fewer spermatozoa penetrate the ovule. Hensen takes the opposite position, namely, that more spermatozoa are utilized in the production of the female than the male. The impregnation which results in the male is supposed to occur later in the history of the ovule, while the impregnation which results in the female probably occurs shortly after the ovule's escape. This proposition is in harmony with Thury's law, and with the practice of many breeders. Dr. Heitzman's conclusion is based upon it, his deduction being, that because the ovule is at that time high up, but comparatively few spermatozoa will be able to reach it. Dr. Heitzman, however, ignores the part of the woman in the sexual act. The commonest complaint of the sterile woman is, "Doctor, I do not keep it. Ought I not to keep it? It runs away from me when I get up." The majority of intelligent women know when they become pregnant. This subject is a new one, but peristalsis of the vagina has been established; the uterus is known to contract under reflex stimulation, especially when applied to the anterior vaginal vault; and it only remains to suggest that the diaphragm is in a position to act as the piston of a suction-pump, the force of which would be exerted upon the contents of the uterus through the Fallopian tubes. Experiments showing how soon after intercourse spermatozoa can be found upon the ovaries will be needed to establish this function; but where all is guess-work it seems not improbable that, at least in the conception of girls, the semen is carried mechanically to the ovule and reaches it at an early date. It may be significant that the conditions at the time of ovulation are favorable to a successful orgasm from the general congestion of the parts.

Hensen's view is not opposed by the fact that the drone is longer in the cell and the male is longer in utero than the female. This retention can result simply from greater size. The horse also remains longer than the boy, and the elephant longer than the horse.

If it be borne in mind that orgasm in the woman is, as a rule, reflex, it will be seen that Hensen's view is not opposed even to the apparent action of Mr. Terry's law.

Hensen's view is also favored by the facts brought out by Dr. Stockton-Hough (*Am. J. Obst.*, February, 1886), namely: That illegitimate children are more frequently girls; that first children are often girls; that conception follows more closely upon marriage, as a rule, where a girl is conceived; also, that female births succeed one another more quickly than male births do. Each of these facts would be completely explained were it assumed that the mother was in a more responsive condition at the time of the intercourse from which the girl was conceived, and Dr. Hough's elaborate deductions would be rendered unnecessary.

Mr. Terry's explanations and Dr. Stockton-Hough's explanations will, however, undoubtedly carry weight, and if they are to result in facilities for the better physical development of any future mother, the present writer will not oppose them. She will simply call the attention of these reformers to a field for work. A contributor to the February number of *Harper's Monthly* tells us that manual training, such as wood and metal work, is being added to the common-school course for boys, and that sewing is being introduced in girls' schools in all grades. It is reported that the boys who formerly would break down toward the close of the term, now go through the year without suffering in health. It is not said what effect the sewing is having upon the girls. Being, as we have seen, pretty hard to kill, they will probably not break down, but will come out with but an exaggeration of the weak voice and the narrow flat chest of the present American girl. To make a seamstress they will have spoiled the mother of future men. If he thinks it over, Mr. Terry will realize that it is not deficient passion in the mother, but deficient breathing-room that cripples his boys. Their nourishment fails, not because her mammary glands are defective, but because her blood cannot furnish the materials from which milk is made.

Would it not be better to keep the sewing out of the schools and to put in its place singing, or something else which will increase instead of diminishing the working capacity of the chest? Properly clothed the girl can handle the plane and use the hammer with as good a result, so far as health is concerned, as the boy, and with as much pleasure in the work.

I will but add an extract from a letter recently received. I will explain that this letter is in the line of this discussion, as it has to do with the disposal of one or more of this surplus female population concerning which complaint has been made. The letter is from a woman, a recent graduate of medicine, and is dated from Bombay, India, where she went about six months ago on her own responsibility, and without promising allegiance to any missionary board. The letter reads: "I have safely arrived in Bombay, as you see, and like the city and climate very much. I find plenty to do. When I arrived here I had used nearly all my money up on the journey, but I soon got patients among the Europeans, although there are already two other women physicians here. I am now able to pay all my expenses, with carriage hire, etc.; but I learn that even here I do not do as well as I might up in the interior of the country. I think that others would do well here. Lady Dufferin is raising a fund to help women physicians to come to India. She can be written to as Her Excellency the Countess of Dufferin, Government House, Calcutta, India. In making an application, testimonials should be sent."

Mr. Editor, with your permission, I will sign myself,

A WOMAN.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 31, 1886, to February 6, 1886.

BROWN, H. E., Major and Surgeon. Granted leave of absence for six months on surgeon's certificate of disability, with permission to leave the Department of the Missouri. S. O. 29, A. G. O., February 4, 1886.

VICKERY, RICHARD S., Major and Surgeon. Assigned to duty in connection with the Army and Navy Hospital at Hot Springs, Ark. S. O. 24, A. G. O., January 29, 1886.

WHITE, ROBERT H., Captain and Assistant Surgeon. Granted two months' leave of absence, to take effect when his department commander may think proper. S. O. 29, A. G. O., February 4, 1886.

CHAPIN, A. R., First Lieutenant and Assistant Surgeon. Relieved from temporary duty at Fort Robinson, Neb., and ordered to rejoin his proper station, Fort Laramie, Wyo. S. O. 11, Department of the Platte, February 2, 1886.

Official List of Changes in the Medical Corps of the United States Navy for the week ending February 6, 1886.

BABIN, H. J., Surgeon. Ordered to U. S. S. Vandalia.

DIXON, W. S., Surgeon. Ordered to Marine Rendezvous, New York, to relieve Surgeon Babin.

WHITING, ROBERT, Passed Assistant Surgeon. Ordered to U. S. S. Vandalia.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 6, 1886:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.

A CURIOUS CASE OF HICCOUGH.—Dr. Charles Liégeois reports a case of singultus occurring suddenly after mental excitement in a woman, and continuing day and night for over three weeks. Milk and bouillon which were given for nourishment were retained on the stomach. Various remedies were given without result, until, on the twenty-fourth day, Dr. Liégeois ordered large doses of chloral and hyoscyamine. During the sleep which followed the hiccough ceased, but returned as soon as the patient awoke. From this time it gradually became less troublesome, and finally ceased entirely, except for short periods following some mental excitement or the ingestion of food. Some months later an abscess appeared in the right epigastric region, and from the opening formed nine needles were extracted. From that time forward the patient was entirely freed from her attacks of singultus. She maintained that she had no idea how the needles had entered her body.—*Journal d'Accouchements*, December 30, 1885.

THE DEATH-RATE AMONG THE RICH IN LONDON is from 12½ to 25 per 1,000. Among the poor it is from 25 to 35½ per 1,000. The average duration of life of the well-to-do in England is 55 years; among the artisan class at Lambeth it was 29½ years.

BACTERIOLOGY AND THE GERM THEORY OF DISEASE.

BY JOSEPH LEIDY, M.D.,

"Nature is infinite, and yet every part of Nature most wonderful in the least of her creations." Truly no more fitting motto could herald the introduction to a subject which has of late seemed to grow in directly inverse ratio to the size of the objects it considers, and which leaves us to-day, after the accumulated evidence of centuries of observation and of painstaking work, just within the vestibule of a science with illimitable vista and boundless possibilities. Hinted at for many years by those whose genius or study lifted them above the plane of their scientific colleagues, it was met by ridicule, scorn and derision, rather than by argument and reason. Facts and theories were alike discarded as being totally unworthy of consideration, much less of belief, and the advanced skepticism of the day did not allow its votaries to entertain the possible truth of a doctrine which seemed, on the face of it, to have so little in its favor.

That the process of evolution, after having through many, many ages continued its undeviating, harmonious action for the highest development of its primitive forms, should have resulted in such an example of perfection as the human body, with its manifold wonders of mechanism and tissue change, was to the scientific mind evidence of the potency of a divine and simple law; but, until within the last few years, these same minds were not prepared to see the completion of that law in the return of the body to its inorganic elements through the restless activity of bodies whose dimensions are almost more than microscopic, and whose organism presents a simplicity of structure which ranks them with the lowest types either of animal or vegetable life.

To us, as physicians, the subject possesses an interest greater by far than the love with which every student of nature follows the new revelations of her mysterious processes. The medicine of the future, as has been well and wisely said, shall find its proper study in the prevention rather than the cure of disease, and we cannot remain indifferent to a study whose aim it is to show that many of the most disastrous morbid processes are so intimately associated with the growth of microscopic life, that we are as yet uncertain of the exact relation between the two. We are not in position to deny that the germ is the cause of disease, but we are not more able to absolutely prove such causal connection, and the most that has been gained for the present is the proof of the frequent, in some cases, constant, coexistence of microscopic organism, and some definite diseased condition.

It is always a matter of interest to trace from their earliest beginning the various steps through which any department of science has reached that degree of completion which makes it serviceable to man; and it would, perhaps, well repay us were we to devote our attention to this part of the subject; but the time is limited, and we are far more interested in what may be called the practical acquisitions—those parts of it which have already passed beyond the domain of speculation and now have secured a firm basis of fact—which are already employed in the detection and cure of disease, or give promise of being thus employed. But no study of the germ theory of disease, or of bacteriology would be complete which would omit a grateful mention of the names of Pasteur, of Lister, Tyndall, of Davaine and Koch. It is not that to these illustrious men is due the only credit, but their names stand out pre-eminently, and will ever be associated with this subject when many others, whose steady application and laborious plodding have contributed so much to its successful unravelling, shall have again been veiled in obscurity.

There seems to be but little relation between the preventive vaccination against *rabies* or *anthrax* and the laws of crystallization of chemical salts: the one being a purely physical process, the other dealing with the most intimate changes of living tissue, the hidden chemistry of the body; and it would have been a more than prophetic vision that would have declared, forty years ago, that there should grow from the laboratory of the Paris school a vast field of study with no lower aim than the successful solution of the causes of disease, and the no less successful discovery of a cure. It was at that time that Pasteur was making his studies of the paratartaric acid; it was at that time that he found that solutions of this salt could, under given conditions, be made to yield two kinds of crystals, one of which deviated the plane of polarization to the right, the other to the left; it was then, also, that he discovered that the introduction into the solution and the multiplication there of microscopic organisms would leave the solution entirely barren of *one* of these salts, which had evidently served as nutriment to the rapidly increasing organism. It was shown to be a constant phenomenon, and by thus first calling attention to the selective agency of these little organisms, it laid one of the great foundation-stones for the subsequent structure.

This discovery was followed, not long after, by the no less important one of the acetic ferment, the ferment of wine, of beer, of lactic and butyric acid. The idea first suggested was quickly followed out, and surprising changes effected by the discoveries in some of the most important and profitable industries of France. The wonderful results that followed the detection of the silkworm disease were not unimportant in their bearing on our subject, since they showed that a disease of the parent, due to the introduction of a living parasite, would manifest itself in the offspring by symptoms of impaired and rapidly-failing vitality.

At the same time that France was showing such remarkable advance in scientific inquiry, Lister, across the Channel, was pursuing a line of study widely different, to all appearances, yet leading to the same result. The process of fermentation in its relation to the development of micro-organisms, and at the same time to the development of unfavorable conditions in open wounds, occupying such a leading part in hospital management, was certainly not an unworthy subject of research. The work of Lister, as it bears upon the so-called antiseptic method, is really part of the medical gospel of the day. No text-book omits the mention of his name, and while increased experience has clearly shown the inutility of many of the details of his complicated method, the underlying principle stands fast as the great triumph of modern surgery. The exaggerated and overscrupulous care in the management of all solutions of

[1] Read before the [illegible] Medical Society.

continuity was necessary, perhaps, to arrest the attention of surgeons and of the general profession to the hidden danger that lurked in every breath of air, and it was reserved for Tyndall to clearly demonstrate the myriads of living forms that travelled in every sunbeam.

There followed then the fruitful studies of Pasteur and Davaine on septicæmia, and the researches of Koch on traumatic infectious diseases. Their bearing on the present aspect of the science cannot be overestimated; they furnished proof of undoubted connection between the disease that was consuming the organism and the parasite that was always found in the diseased tissue; they made the cultivation-experiments, and from their purely artificial cultures obtained the same results as those which followed the inoculation of the virus, clearly establishing the identity of the organisms under both conditions.

There is even a more remarkable tie that binds our present subject with one of older date, also seemingly widely apart from any such delicate manipulations. The discovery of the aniline colors may be really said to have given the greatest impetus to labors that, without their use, would have proved, almost certainly, barren of result; and again we find verified, in this particular, a saying of Waldeyer, that advance sin histology are marked by the introduction of new coloring matters, and the ultimate anatomy of any tissue is finally revealed to us through the agency of *the* particular staining fluid for which individual details have a greater or less affinity. To-day, with many other means of research at command, the peculiar reactions with different aniline dyes constitute an important element in the distinction of micro-organisms resembling each other in nearly all other particulars.

It is not our province to speak of the methods of cultivation, nor of the facts revealed in this way; and we enter at once upon the proper consideration of what is meant by bacteriology. To define it by an almost similar term, it is the science which treats of bacteria; and *bacteria*, according to the definition of Dujardin-Beaumetz, "including in this word all the microbes or figured ferments, are certain minute living forms, placed on the confines of the animal and vegetable kingdoms." At the present day the general view is to regard them, as first suggested by Cohn, as vegetable organisms. To simplify their study many schemes of classification have been suggested. The first and very incomplete one of Ehrenberg has been entirely discarded, and the view of Nägeli and Barry, that they were moulds, is at variance with that of Cohn, who regards them as more closely allied to the algæ than the fungi. The very elaborate classification of Cohn, resting upon a purely morphological basis will, in all probability, not hold for many more years; and until we shall know more of the so-called life-conditions, the circumstances which favor or retard their growth and reproduction, it will be impossible for us to give this microscropic world a comprehensive and rational scheme, like that which governs our study of other branches of natural history.

At the very outset, we encounter divergence of opinion on a most important point, as to the resemblance of parent and offspring—Klebs upholding the view that such resemblance always exists, Cohn holding that many different forms, depending for their individuality on surrounding circumstances, may owe their origin to the same parent. The physiological basis, that which treats of these bodies in reference to the results of their activity in and outside of the body, is the only one that offers itself as satisfactory, but our knowledge is too limited to enable us to make from this a comprehensive scheme.

Morphologically, Dujardin Beaumetz, whose valuable contribution has furnished much of the material of this sketch, recognizes six forms: (1) Monad, micrococcus, or moner, immobile point-like microbes, often regarded as spores. (2) Bacteridia and bacillus, immobile linear microbes. (3) Bacteriens, cylindrical mobile microbes, the end rounded, or the body indented in the centre, so as to form a figure of 8. (4) Vibriones, eel-shaped, undulating, mobile, and flexuous microbes. (5) Spirilla and spirochetæ, corkscrew-like, spirally moving microbes. (6) Capitated microbes, *bacterium capitatum*, being mobile rods, with one or both extremities long, globular, and more refractive than the rest of the body.

This classification has reference to the cells as seen singly or in very limited numbers, when aggregated so as to form colonies there are distinguished four forms:

1. Torula, in the form of a necklace, composed of micrococci.

2. Leptothrix, made up of bacteria, clustered end to end.

3. Mycoderma, immobile, composed of bacteria in sheets.

4. Zoöglœa, being masses of bacteria, immobile, inclosed in a sort of jelly which holds them together.

Pasteur again has divided into two grand classes all these little organs, the aërobiens, which are not ferments and require the ready access of free oxygen, the anaërobiens, or ferments which abstract from their culture-medium the oxygen necessary for their life, thereby giving rise to the fermentative changes, or decompositions; because in fermentation the resulting compounds are always simpler in chemical composition than the parent substance, liquid or solid. This theory as to the action of the ferments has, however, received some very severe shocks, and can no longer be deemed secure. Thus it was shown that in the fermentation of sugar the resulting products, alcohol and carbonic acid gas, etc., contain together as much oxygen as the sugar; moreover, purely artificial chemical action, as of an acid, will produce alcohol from sugar in the same way. In addition, too, to this, the process of fermentation always goes on most readily where there is abundance of oxygen admitted, so that large, flat vessels with considerable surface-exposure yield the best results. This should not be the case were the attraction of the oxygen of the culture-fluid for the bacteria of fermentation greater than that of free oxygen.

It is under the name suggested by Nägeli, "schizomycetes," that the bacteria which stand in an immediate relation to morbid processes in the human economy are now most generally known. The nature of this relation has not as yet been determined in any case, though it constitutes the key to the entire question. The schizomycetes are nearly all possessed of the power of independent movement, which is in some cases very rapid. Mühlhauser has measured it for the spirilla, and found it to equal one-third of a millimetre per second. Like nearly all other lowly-organized forms, they move toward light and air. The movement in many of these organisms is effected by a sort of cilia or flagellum, attached to one or both extremities, the mode of progression being usually by alternate flexion and extension of this process or of the entire organism; in the case of the spirilla by a helicoid rotation.

In the process of multiplication we find their numbers increase by simple fission. The parent organization divides into two parts, which may, or may not remain joined together, and each of these then undergoes a similar subdivision. When the separation does not occur, a number of single segments are united in a long chain, forming what is known as strepto-coccus or strepto-bacteria. In some cases, particularly where growth is very rapid, multiplication takes place by spores; when only one or two of these are formed, they are usually situated near the extremity of the parent organism and sometimes produce a sort of bulbous enlargement; if more numerous, they may be found throughout the entire length, and have under these circumstances given rise to the mistaken conception of a number of micrococci joined together. The spores seem to possess much greater powers of resistance than the parent; neither alcohol, boiling heat, nor compressed oxygen interfere in any way with their vitality.

These asexual spores or "corpuscle germs," are most prone to develop in just those conditions which render

the direct multiplication by fission difficult or impossible; and they thus, in a measure, constitute a safeguard against the extinction of the species.

The influence of temperature on the life processes of bacteria is most marked. Nearly all of them are destroyed in a very short time by high temperatures.

Koch and Wolffhügel, as the outcome of a number of most carefully conducted experiments, report the following conclusions:

1. Bacilli without spores are incapable of withstanding the influence of an atmosphere heated to 100° C. for one hour and a half.

2. Spores of the fungi require for their destruction a temperature of 110°–115° C. (220°–230° F.) continued for one hour and a half.

3. Spores of bacilli are only destroyed by remaining for three hours in an atmosphere heated to 140° C. (284° F.).

4. In a heated atmosphere the heat enters the objects to be disinfected so slowly that after exposure to 140° C. (284° F.) for from three to four hours, objects of moderate dimensions, such as a bundle of clothes or a pillow are not yet disinfected.

5. The application of such a heat, 140° C. (284° F.), for three hours or more, as is necessary for complete disinfection, is more or less injurious to most textile fabrics.

In another essay of the same collection it is stated that in all cases where heat is at all applicable as a means of disinfection, the method of employing steam and closed apparatus is much to be preferred to any other method. Generally, as stated by Dujardin-Beaumetz, the bacteria are destroyed by a temperature of from 144°–160° F.

The bacteria do not flourish equally well in all culture-mediums, and the differences in this respect have frequently been relied upon, where other criteria were absent, to decide the question of the unity or dissimilarity of otherwise similar forms. It has been argued that the same parasite will at all times thrive equally well upon the same kind of sustenance, and that, other physical conditions being the same, the results in culture experiments should be the same. Reference has already been made to the splitting up of paratartaric acid, and instances might perhaps be multiplied to show that if a given solution be prepared containing the proper food of a certain bacterium, and many other substances in addition, only that substance will be consumed for which the affinity of the organism is well established. Quoting from Dujardin-Beaumetz, "the differences between the respective living ferments, such as the alcoholic, tartaric, and acetic, etc., are of just this character, that each, according to its own constitution, thrives on some particular nutrient ingredient, which it assimilates and disassimilates at will, while it dies in another medium not suited to *it*, but which is perfectly suited to some other ferment organism. In like manner the pathogenetic action of the schizomycetes is limited to this power of organic disintegration, in which they act the parts of ferments in furtherance of their own nutrition."

It is not long since that Brieger discovered in the human cadaver a number of organic alkaloids to which he gave the name of Ptomaines, and which he found to possess the greatest virulence, and to resemble in chemical reaction many of the more powerful vegetable poisons. Now it has been found that such ptomaines are formed where bacilli are undergoing rapid proliferation, and the theory has been advanced to harmonize many antagonistic views, that the bacterium is the cause of disease through the intervention of the ptomaine, which is itself the product of the bacterium. This theory would explain many experimental results, such as those of Rosenberg in pyæmia, where a culture-fluid was artificially filled with bacteria, the fluid carefully filtered, the filtrate found to be devoid of living organisms, and yet when injected hypodermatically this same fluid was found to be as potent in the production of the characteristic changes of pyæmia as though the specific micrococci had been present. It would be easy to determine which of the two—the bacteria or its soluble product—is the cause of disease, were it possible to isolate the two completely; we can obtain the pure ptomaine in solution, but we cannot conceive of the bacterium freed from the ptomaine. Were we to accept this theory, we could also explain satisfactorily the results obtained by Koubasoff "on the passage of pathogenetic microbes from the mother to the fœtus, and their occurrence in the milk. He has formulated the results of his experiments in a note recently addressed to the French Academy of Sciences as follows:

1. Bacilli of charbon, of rouget, and of tuberculosis, when inoculated into a recently delivered female pass into the lacteal secretion.

2. When they have once appeared in the milk they remain there to the end of lactation and to the death of the mother.

3. Fœtuses nourished with milk containing the bacilli of charbon, of rouget, or of tuberculosis do not take the disease, and remain alive even when their mothers die of the disease.

4. The passage of microbes from the mother to the fœtus probably depends upon the existence of direct communication between the maternal and fœtal vessels in the placenta. It would not require the entrance of the formed organism to produce the fœtal disease, if, according to the view above indicated, a soluble poison passed with the nourishing blood by osmosis through the vessel-wall.

Bacteria of various kinds are constantly found, not only in the earth, air, and water surrounding us, but in all cavities of the body itself, and one enterprising observer, Stahl, found only twenty-five different and distinct forms of micro-organisms in the intestinal contents, including several varieties of mucedo, yeast, micrococci, and bacilli; and the author seriously states that if he had only tried he would probably have found several more.

I do not propose to enter into a separate and detailed study of the single diseases in which bacteria have been found to play a rôle; such a course would lead us far beyond the legitimate limits of this paper, and it will suffice to enumerate anthrax, chicken-cholera, the swine plague, hydrophobia, pébrine of silk-worms, flacherie of silk-worms, septicæmia, pyæmia, puerperal fever, malarial fever, recurrent fever, pneumo-enteritis of the hog, small-pox, glanders, sheep-pox, measles, scarlet fever, erysipelas, yellow fever, typhoid fever, cholera, croupous pneumonia, gonorrhœa, syphilis, diarrhœa and dysentery, ulcerative endocarditis and tuberculosis, to show that the list embraces quite a respectable part of those diseases which are of almost daily occurrence, and come under daily personal study. For a few of these, as for chicken-cholera, anthrax, and tuberculosis, the association of the bacillus and the diseased process is fairly proved; but for the others, a weight of most conflicting testimony can be gathered. I cite only two examples, syphilis and pneumonia. The idea of the parasitic origin of syphilis was strongly upheld by Lostofer, of Vienna, some twenty years ago, and it again falls to the lot of Vienna to claim the discoverer of the modern germ. On the 12th of November, 1884, Lustgarten reported to the Imperial Society of Physicians his discovery of the bacillus of syphilis; and subsequent researches seem to have confirmed its existence, if not its specificity. Such confirmatory evidence was furnished by Doutrelepont and Schütz, Lustgarten's later studies, by Giacomi, and finally the test-experiment of Babis and Leloir, which showed the presence of the bacillus in microscopic sections of chancre, mucous patches, and in the secretions from syphilitic sores, properly dried and stained.

No cultivation experiments to determine its specific identity had as yet succeeded, when Alvarez and Travel undertook a series of researches in the laboratory of Cornil. They examined a number of sections made from eight cases of syphilis (five hard chancres, two mucous

patches, and one gumma), and were not able to find the bacillus; and in twenty-two cases out of fifty-five preparations of syphilitic secretion the result was negative. Moreover, they discovered bacilli like the syphilis bacillus of Lustgarten in a number of non-syphilitic secretions, in cases of soft chancre, of genital herpes, of pemphigus of the thigh, and more especially present in the smegma. This bacillus of smegma has also a great resemblance to that of tuberculosis, especially in regard to its reaction with staining fluids. It differs from it in being thinner, less granular in aspect, frequently having an S-shaped incurvation, and in its polymorphism. Like other experimenters, Alvarez and Travel have not been successful in obtaining cultures.

We have here two opinions, or rather observations, that flatly contradict each other, on a subject that is constantly being most thoroughly studied. How is it with pneumonia?

In 1883 Friedländer described his micrococcus of pneumonia, or pneumococcus, as being a body of elliptical form and giving certain reactions with fuchsine and gentian violet In later publications he lays less stress on the form of the microbe, and attaches a pathognomonic value to a sort of mucous capsule which surrounds it, and which, he says, is always present in the microbes of frank or fibrinous pneumonia, but not present in other forms of pneumonia, where we may have micrococci but no capsules surrounding them. He even describes empty capsules, from which the coccus has escaped. And now comes Dr. George Sternberg, probably the most competent authority on the subject in this country, and sums up the data of a rather lengthy but interesting article as follows:

"The pneumonia-coccus of Friedländer is identical specifically with the micrococcus previously described by me, and which is commonly found in normal human saliva. The capsule, or mucous envelope, which sometimes surrounds this micrococcus, described by Friedländer in 1883, and photographed by me two years previously, *cannot* be accepted as a distinguishing character of this species, inasmuch as it is not constantly present, and the circumstances upon which its development depends have not been accurately determined. It is established that it is a pathogenic organism, so far as certain lower animals are concerned, and that its pathogenic power varies under different circumstances. It seems extremely probable that this micrococcus is concerned in the etiology of croupous pneumonia, and that the infectious nature of this disease is due to its presence in the fibrinous exudate into the pulmonary alveoli."

But this cannot be considered as definitely established by the experiments which have thus far been made on the lower animals. The constant presence of this micrococcus in the buccal secretions of healthy persons indicates that some other factor is required for the development of an attack of pneumonia; and it seems that this other factor acts by reducing the vital resisting power of the pulmonary tissues, and thus making them vulnerable to the attacks of the microbe. This supposition enables us to account for the development of the numerous cases of pneumonia which cannot be traced to infection from without. The germ being always present, auto-infection is liable to occur, when, from alcoholism, sewer-gas poisoning, crowd poisoning, or any other depressing agency, the vitality of the tissues is reduced below the resisting point. We may suppose, also, that a reflex vaso-motor paralysis, affecting a single lobe of the lungs, for example, and induced by exposure to cold, may so reduce the resisting power of the pulmonary tissue as to permit this micrococcus to produce its characteristic effects.

Again, we may suppose that a person, whose vital resisting power is reduced by any of the causes mentioned, may be attacked by pneumonia from external infection with material containing a pathogenic variety of this micrococcus having a potency, permanent or acquired, greater than that possessed by the same organism in normal buccal secretions; the author then supplements these statements with a number of experimental observations to show the identity of the two organisms. It must be clear from this that the micrococcus cannot be the determining cause, and if it be not, what have we gained from our knowledge of its presence? Many means have been devised to protect, if possible, the human body from the malevolent agency of this specific micro-organism, which enters, none knows how, and which does such grave and irreparable mischief. Experiments have multiplied without limit to illustrate the remarkably effective action of the various antiseptics, and while one has extolled bichloride of mercury, and another carbolic acid, a third has found in sunlight a powerful germicide. It is not easy to see what benefit the profession is to derive from the fact that a solution of bichloride of mercury, in the strength of 1 to 20,000, poured over an artificial culture of bacteria will arrest their further development. It would be rather uncomfortable, aside from the actual difficulties of accomplishing this result, to move about continually in a *nebula* of bichloride spray, as though every man were his own atomizer.

To the indefatigable, indomitable spirit of Pasteur we are again indebted for the only results worthy of mention in this direction. Triumphing over physical difficulties which would in another have constituted a crushing blow to all energy, he has lived to see the closing years of his life equalling, if not surpassing, in their usefulness, any former period of his existence. The method of vaccination with attenuated virus has astonished the entire scientific world by the accuracy and trustworthiness of its results. The pasture-field of Mélun was the Austerlitz of his scientific labors; the results obtained in the case of charbon were further strengthened by the successful vaccination against chicken cholera, which preceded them only a short time, and as third in the list we have the verdict of a commission of inquiry, appointed by the French Academy, that the report of M. Pasteur, as to the successful vaccination against rabies, is in every way satisfactory, and amply borne out by experiments submitted to the commission. Any one of these achievements would have sufficed to fill the measure of an ordinary life; taken together with his previous work, they constitute a record of devote l usefulness that few, if any, have ever equalled, and whose practical value each succeeding age will the more fully appreciate and honor.

It was slightly in the nature of a disappointment to read over the lengthy report of the proceedings of the second Cholera Conference held recently at Berlin. Scarcely any new developments have attended the studies of the past twelvemonth. A very large part of the discussion was taken up by Koch's refutation of the attacks of Finkler, Prior, and Klein. It was only natural that the bacillus dinner of the last-named observer should have wounded the sensibilities of the genial patron of the comma-bacillus, and should have led to a reassertion of priority in the discovery, as well as of the authenticity of previously asserted facts. It is a point of some significance that Koch himself admitted a doubt as to whether there was any permanent form of the cholera bacillus.

It would seem that his argument was not entirely convincing, for von Pettenkofer still adhered to his old view, that the bacillus could not be the cause of the disease, as proved by the history of various epidemics; that cholera was not in any sense contagious, and that the rise and fall in the level of the subsoil water were points of great importance in determining the occurrence and severity of epidemics.

In rejoinder, Koch stated that direct contagion was rare, but that germs required clothing or some other material to perfect their growth before becoming noxious. Virchow also opposed the doctrine of direct transmission to man from the soil, as in the case of malaria, and sug-

gested as a sort of compromise that bacilli might grow in the earth, in agar-agar, and soiled clothing.

Nor was there any new feature brought out with reference to prophylaxis. Koch advocated disinfection of clothing, careful cooking of food, cleanliness, and the free use of carbolic acid, which seemed to him the best disinfectant. Von Pettenkofer cited the history of the epidemic of 1836, very mild in its character, during which scarcely any precautions were taken by the people of Munich and Bavaria in general, as the disease was then regarded as non-contagious, and he did not see any cause for anxiety, even though thorough disinfection could not be carried out.

In a communication made to the *Progrès Médical* of last year, Babis states that in nine cases examined by him the comma bacillus was found almost every time in the fæces and in the material taken from the surface of the mucous membrane of the intestine. Artificial cultivations were made after the method of Koch, and on gelatinized plates, and it was found that the development begins at a temperature of 70°, fifteen to eighteen hours after the beginning of the experiment. After twenty hours we find the characteristic appearances. In the development the following appearances are easily recognized with a magnifying power of ten diameters: In the centre there is a point formed by a mass of dust, around it a first granular circle, and outside of this a second, more clearly defined, more granular circle. Between these two circles the gelatine is liquefied, probably the result of the chemical changes due to the bacilli.

These cultures have a more yellowish appearance than the cultures of other microbes of the fæces, they are more transparent, their circles are larger, their central point smaller. After thirty hours several cultures unite, and finally become entirely fused, the regular outline is lost, the gelatine is partially liquefied, and little flakes float in it If we inoculate a gelatine tube with platinum the culture appears two days later as a grayish mass, with excavated granular surfaces, conical in shape, the apex directed toward the base of the tube, with a whitish globular prolongation at its tip. If the gelatine be very concentrated, a bubble of air will always form at the surface, and the characteristic form appears below.

Cultures were also made on milk, coffee, meat, carrots, vegetables, eggs, bouillon, and potatoes. The bacillus does not grow on fresh, boiled, or dried fruits, on acid liquids, on beer or wine, on preserves containing but a small amount of liquid, on cheese, on salt or smoked meat. The bacilli, when dried on a slide, die after twenty minutes. Unless the culture-medium be thoroughly sterilized the bacillus develops badly or not at all.

By using agar-agar in place of gelatine, cultures can be obtained in ten hours, but these are less characteristic than the gelatine plates. Beef serum gives opaque, globular, but still characteristic cultures. Distilled water is not a favorable culture-medium, as neither bacilli nor other effects of inoculation are apparent after twenty-four hours.

In liquefied gelatine we find that after twenty-four hours the bacilli are animated, and perform very decided movements, oscillatory in character, like those of spermatozoa.

In regard to morphology, we find that they are readily colored by diluted methyl-violet (1 part to 200). After ten hours on agar-agar, the culture-bacilli, though smaller than the fully developed organism, are already curved. After twenty hours we find bacilli measuring 0.4 mm. to 0.5 mm. in thickness for 1.5 mm. in length. It is particularly by adopting this device that the bacillus looks like a comma with concavity and convexity; one end is often thrown upon the end of the next adjoining bacillus, so that the two frequently remain joined like the letter S.

I would especially refer to one sentence of this admirable description. "Unless the culture-medium be thoroughly sterilized the bacillus develops badly or not at all." Where in nature do we find sterilized media? What collection of water affords, under these conditions, a favorable nidus? For, according to Koch, it is the pollution of the water which is the principal cause of the spread of epidemics; and I refer just to this one instance to point out how little has been gained of the natural laws of life of these organisms, when left to those surroundings which nature has given them. Neither the soil, nor air, nor water are ever sterile, and yet, if we are to accept the bacterial origin of cholera, we must look to one of these as the temporary abode of the organism, where its development and multiplication occur.

In the introduction to the one hundred and first volume of his celebrated *Archiv*, Professor Virchow, in an article entitled "The Struggle of the Cells and the Bacteria," says: "The intellectual movement is now so active, the number of new questions daily coming to the surface so great, the multitude of experiences of all kinds so confusing, that it might seem indicated to issue a new watchword, to point the direction according to which this colossal accumulation of material shall be arranged." Referring to the tendency of all scientists to subvert every other doctrine to the action of physical and chemical forces, a doctrine which prevailed about forty years ago, when the *Archiv* first appeared, he says that then particular courage was necessary to think of life as something apart from purely physical or chemical processes. Further on we find the following: "It matters little what the explanation, if any, that some later day may bring of the ultimate cause of life on a physical or chemical basis; plants and animals, cells and tissues will still have to be acknowledged to be peculiar arrangements of complicated structure, entitled to be considered and judged of according to their own proper individuality." "The hereditary character of life is now the basis of every system of biology." "The natural consequence of the studies in cellular pathology was a certain personification of the cell." Speaking of the enthusiasm created by the discoveries of organisms in such processes as the muscardine disease of silk-worms by Bassi in 1835, the parasite of favus by Schönlein in 1839, of muguet by Vogel in 1841, of anthrax by Davaine, Pollender, and Brauell in the period from 1854 to 1857, of variola and vaccinia by Keber in 1868, and of recurrent fever by Obermeier in 1873, he says, and says well, that a number of youthful explorers at once entered upon the field, and soon the world was full of remarkable discoveries from this *terra incognita*. Each new species was promptly heralded and three questions always came up for answer. First, there was the question as to the actual discovery of the parasite; secondly came the study of its mode of life; and thirdly, most difficult of all, how does it produce the disease? This third inquiry always brings us back again to the old pathology, and the cellular doctrine, of which Virchow can justly speak with pride as his creation, again asserts its right to the foremost rank.

"The proof of specific organisms is still wanting for a whole series of diseases, particularly for those which are most common, infectious, and contagious. And were this proof given, it would be but the first step in the recognition of the morbid process itself. What have pathology or therapeutics gained in the simple demonstration of a micrococcus or bacterium? Do we know anything more of the nature of recurrent fever since we have found the spirillum?

"The reversion to the old pathology is well exemplified in the history of phthisis. When Koch had discovered the tubercle bacillus, many thought that all the laborious research of the past was vain and superfluous. There was unity of the bacillus, ergo—unity of phthisis. But this beautifully simple scheme was of short existence. Pulmonary phthisis remains as it was, a multifarious process, beginning in a number of ways—now in the mucosa of the air-passages, now in the interior of the alveoli, now in the parenchyma of the lungs, and resulting in a variety of products, either simply inflammatory or specifically tubercular; and he who wishes to understand it

must learn something more than how to stain bacilli. The bacillus has added so little to our knowledge of the subject that we are now again arrived at the examination of those two indispensable factors, predisposition and immunity."

Similarly with leprosy, nothing has been gained in the diagnosis, prognosis, or cure of this disease. We will do well to pause at these words of the great pathologist. Do they not convey to us a serious, thoughtful warning? Is there not too marked a tendency to neglect all else in the eager search for more bacteria, more bacilli, more specific organisms, and hence specific diseases? Dr. Jacobi, in some very pertinent remarks at a recent meeting of the New York Academy of Medicine, said: "Obermeier found a bacillus in relapsing fever at a certain period in the disease, but it had not been proven that it was the cause of the disease. It had not been found in the beginning of the disease; but even if it had been found at that period, it would be doubtful whether it was the cause or whether the disease was due to causes which were aroused by the bacillus, or whether the bacillus was the result of the disease. He did not believe we were justified in saying that the bacillus of relapsing fever was the cause of the disease."

With regard to other diseases, microscopists had been anxious to find bacilli, and thus Gaffky had his bacillus, and Klebs had his bacillus, and so on. So with reference to diphtheria, Klebs had his bacillus, which he assured us was the cause of diphtheria; Eberth discovered his bacillus, which he also said was the cause of diphtheria; and even so cool-headed and sound a man as Gerhardt was led to make the statement, only a few years ago, that undoubtedly diphtheria was a bacillus disease; but as Klebs had discovered one bacillus, and Eberth had found his bacillus, he declared that it was probable that two different bacilli could be the cause of diphtheria.

These are no idle comments, and they may be regarded as an expression of a weighty, conservative opinion, that sees but too clearly how, in the first intoxication of a supposed great victory, the tendency may be to the extreme, and may lead to neglect of serious and pressing work.

Continuing with the article of Virchow, it is stated that "the name of the Struggle of the Cells and Bacteria has been applied by the author to that circumstance the clearing up of which is the actual object of medical studies of this class of diseases We have here two living micro-organisms arrayed against each other. Both are endowed with independent life, independent activity, and independent strength. Which is the attacking party? How does it attack? These are the questions awaiting solution."

"It will be a problem for future study to determine more carefully than has yet been done the powers of resistance of the cells and the mechanism of their struggle for self-protection."

In closing he says: "We do not wish to underestimate the value of any pathological studies, but let no man forget that etiology is merely preliminary to the study of pathology, and pathology shall only be complete when the diseased process, that is, the entire course of the disordered vital activity, shall be clearly explained."

To those who have, like many of ourselves, regarded the rapid development of the science of bacterioloy with never-ceasing interest, and with as little bias as possible, though, at the same time precluded by outward circumstances from personally engaging in experiment, the many new discoveries have seemed almost bewildering. The difficulties were not lessened when experimenter No. 2 found some discrepancy in the experiments of No. 1, to be himself corrected and mildly denounced by experimenter No. 3, and so on; and it is only left for us to express the hope, while fully appreciative of all that has been done, while clearly conscious that enthusiasm is the main-spring of action in a field of study that begins and ends with the maxim "Patience," while eager, with the rest of the profession, to score another triumph for our modern medicine—it is only left for us to hope that an early day may witness the advent of that genius to whose clear and comprehensive intellect it shall be given to dispel doubt and darkness, and whose words shall be as the fulfilment of that first and greatest of divine commands, "Let there be light."

THE RADICAL TREATMENT OF VARICOCELE AND OF HYDROCELE,[1]

Reduced to what Appears to be Nearly Ultimate Simplicity.

By E. L. KEYES, M.D.,

NEW YORK.

In venturing upon a subject so trite as the radical treatment of hydrocele and varicocele, I have only to offer as an apology my own experience, and the uncomfortable road I took to reach a conclusion, and to state that the various reports of debates in societies,[2] the histories of cases, and articles in the medical journals upon these subjects that are constantly meeting my eye up to this date, show that the old-fashioned (as I consider them, clumsy) methods still prevail in the profession at large.

These minor maladies are annoying and of very common occurrence. Any one may cure them, and cure them radically, too; but to cure them neatly, promptly, and with little or no pain to the patient, a confinement of only a few days, perhaps no confinement, and with no annoyance to the surgeon—this end I believe has not yet been generally reached by the profession, and as an effort to attain such a result this paper is written.

I believe that any one who has enough surgical knowledge to make a diagnosis of the conditions I propose to consider, and enough mechanical ability to administer a hypodermic injection, can treat hydrocele and varicocele radically and safely by the methods I am about to advocate; and that those who have used other methods will find these more satisfactory to themselves and to their patients.

My personal experience is, as I have said, my reason for reaching this conclusion. I have been in close connection with the study and the treatment of the diseases of the genito-urinary apparatus in the male for the past twenty years. I have performed many, perhaps most, of those operations which are believed to be most suitable for the radical cure of the maladies we are considering. I have tortured my patients and have encountered, personally, annoyance, dissatisfaction, and discomfort in many instances while attaining the radical cure, until I adopted the methods I am now about to explain. Since then I have known comfort, and my patients have tasted peace.

To commence with varicocele. It would be idle for me, in the few minutes at my disposal, to enter at all deeply into the history of this malady, its causes or its symptoms, the innumerable operations proposed for its relief, or a consideration of such questions as the advisability of any operation at all, the risk of phlebitis, of atrophy of the testicle, and of failure to relieve the symptoms, even when the operation is carried to a successful issue. I must assume, in a given case, that varicocele exists, and that some radical operation is to be performed. What, then, is the best operation, and how is it to be done?

I must say here, however, that early in my professional life I was educated to look upon varicocele as a trifling physical irregularity, and its symptoms as mainly subjective in character, and due in great part to general nervous causes and to improper sexual hygiene. Added to this, I early encountered several cases where the radical opera-

[1] Read before the Medical Society of the State of New York, February, 1886.

[2] London Lancet, January 16, 1886, p. 139.

tion, performed by able hands, had failed in effecting a cure of the symptoms (of a nervous order) for which it was undertaken, and notably one case, in which ligation of the vessels by a competent surgeon had been followed by total atrophy of the testicle.

This deterred me for a time; but finally I was obliged to operate. My first efforts were directed toward curtailing the scrotum. This I soon abandoned. The patient had to be confined to his bed, generally for several weeks, and the final result was little better than what a suspensory bandage would afford; while the annoyance to the patient and surgeon were altogether too considerable to be repaid by the result. Then I went through several operations by ligature and silver wire, and by cutting open the scrotum and tying the vessels with catgut and dressing antiseptically; but the pain, or the suppuration, the annoyance, and the long confinement to bed, quickly dissatisfied me with all these operative manœuvres.

Then it was that I first attempted subcutaneous ligature of the dilated veins with catgut, led to it by my use of catgut in general antiseptic surgery; and since my first operation by this method I have never performed any other. I do not know who first ligated the veins of the spermatic cord subcutaneously, or when he did it. Doubtless many have done it, and probably before my first operation; I do not know. I have read somewhere that even carbolized silk was used on one occasion subcutaneously with good result, but I do not remember that I ever saw in print any description of any particular method of applying the catgut; and it is a method that I now propose to explain, since I personally have had a number of different needles made, and have applied the ligature in a variety of ways, and have found finally one method which I believe to be better than others. I have applied subcutaneous ligature with an ordinary straight surgeon's needle, and with various complicated double needles. In every case the operation has succeeded, but only one method has been satisfactory to me, and this I propose to describe.

My first operation was performed in the early summer of 1882. I kept my patient in bed a little more than a week. He recovered without suppuration or serious pain, and I sent him home to Pennsylvania during the second week. A year later he wrote, expressing thanks and attesting the satisfactory result of the operation.

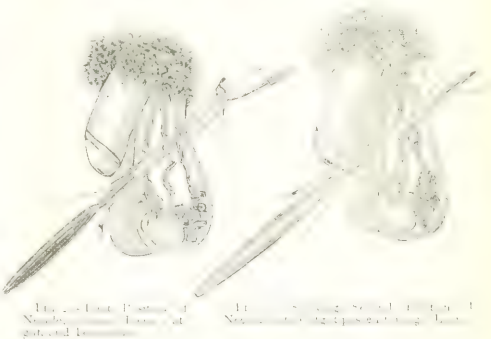
This encouraged me, and I began to feel a new confidence in the operation and to perform it occasionally as cases appeared. I have operated upon a number of patients since the autumn of 1883—all in private life, no hospital cases—and I have uniformly had the same experience.

After the ligature is applied some pain is experienced, a hard lump enclosing the veins appears in twenty-four hours, varying in size from half an inch in diameter up to the dimensions of a pullet's egg. There is usually some scrotal ecchymosis, and generally a little tenderness of the testicle upon handling. I have never seen a single drop of pus. I usually give no medicine except a laxative when required. I make no local application, simply swinging up the testicle by a bandage to take the weight off the cord. Some of my patients have left the bed upon the second day. I try to keep them quiet for five days, and rarely do I find it necessary to give any anodyne whatsoever during the treatment. The hard lump about the veins subsides with varying rapidity while the patient is about, wearing a suspensory bandage. It is practically gone in a month (in cases of moderate swelling), but traces of it may be felt for a year or longer. I believe the veins to be always permanently occluded. I cannot say that suppuration or other complication is impossible when this operation is performed, for my dozen cases (or thereabouts) cannot justify such a generalization. But I have not yet seen a complication, and I believe that, with care in operating, better success with less probability of complication is presented by this operation than by any other I know.

The operative method is as follows: I have always used carbolized catgut, one-half millimetre in diameter (but I am contemplating the use of the finer, tougher, and more flexible whale-tendon). I have two varieties of needles, both straight needles in handles (Fig. 1), about size 4 of the French urethral gauge in the shaft. One has a lance-shaped point, the other a point like a

hypodermic needle. The former I prefer when any of the thickened tissues of the cord have to be pierced, the latter when a single large vein can be isolated from all other tissues—as is sometimes the case. Both needles have a long eye. The needle is threaded with a loop of silk, or thin whale-tendon (carbolized), and a piece of carbolized catgut.

The scrotum is to be thoroughly washed with a solution of the bichloride of mercury, one in one thousand, and all instruments, ligatures, and the operator's hands to be soaked constantly in the same solution. Ether is not admissible, as the patient must stand up. A few drops of a four per cent. solution of cocaine, thrown under the skin near the point of proposed puncture, will nullify the pain in the case of exceptionally nervous patients. Many people feel faint when any operation is done about the genitals, the cause being seemingly more moral than physical; for the pain of this operation is not severe. After the first puncture, faintness on the part of the patient is no bar to a successful completion of the operation, for the patient may be then placed on his back and the operation finished, with a certainty that the dilated veins are included in the ligature, if only the first puncture has been successfully made.



The patient stands near the bed, in a good light. The veins which it is proposed to occlude are separated in the usual manner from the rest of the spermatic cord, at a point rather high up, where the separate dilated trunks may be made out as straight and not convoluted dilated channels. The big veins are pushed out toward the thigh of the affected side, and the scrotal tissues between the veins and the rest of the cord are tightly pinched by the thumb and finger of the operator's left hand, placed behind and in front of the scrotum.

Now the needle, properly armed, is boldly thrust through the scrotal tissues from before backward at the point pinched, leaving the veins on the outer side of the needle toward the thigh. The eye of the needle is made to emerge at the back of the scrotum. A tenaculum seizes the catgut ligature and pulls it out of the eye of

the needle, leaving it sticking out freely from the posterior wound alongside the shaft of the needle.

Now the point of the needle is withdrawn within the scrotum, leaving the catgut end outside. The veins are allowed to join the rest of the spermatic cord. The point of the needle is not to be withdrawn outside of the anterior point of puncture in the scrotum.

When the veins have passed internally to the point of the needle, the latter, still charged with its loop of silk or whale-tendon, is manipulated around externally to the veins under the scrotal integument, and is made to emerge accurately at the posterior hole, the original point of puncture in the scrotum. This is the most important step in the operation, and the only one at all difficult to execute nicely.

When the eye of the needle has emerged posteriorly charged with its loop of silk, the tenaculum again is called into play to loosen the loop and to draw through it the free end of the catgut which was left at the first puncture protruding posteriorly from the scrotum.

The parts are again dashed with the antiseptic bichloride solution, and the needle and loop (containing the catgut) are rapidly withdrawn.

Now it will be found that a few filaments of the dartos (or other tissue) just within the posterior wound in the scrotum are included in the catgut loop. These are torn away by simply holding the free ends of the catgut in front and pulling upon the scrotum behind (Fig. 4). The thin tissues will be felt to tear, and the patient will complain of a little pain.

Fig. 4.

Fig. 5.

Finally, the few hairs about the anterior wound are to be seized with the thumb and finger and pulled out—else they certainly will be tied into the knot and cause trouble—and the catgut (again drenched with bichloride solution) is tied tightly into a triple knot, cut off short, and the scrotum pulled away. The knot sinks out of sight, and the operation is terminated by placing small pieces of plaster over the minute points of puncture, if any blood exudes (Fig. 5).

If the operation is well done, in twenty-four hours it is difficult to detect the points of puncture.

The operation for hydrocele is even more simple, and is much easier to perform.

Again, I need not dilate upon the radical methods in common use—the injection of iodine, laying open the sac anteriorly with the knife, or its modern modification, the so-called Volkmann's operation. All of these and many others I have done frequently, and have been dissatisfied on account of the pain suffered by the patient, the dirtiness of the operation, or the necessary confinement to bed—amounting often to several weeks.

Since Dr. Levis,[1] of Philadelphia, some five or six years ago, made known the excellent qualities of pure deliquesced carbolic acid as an injection for the (comparatively) painless and very certain cure of hydrocele, I have employed no other material in any case of simple hydrocele of the tunica vaginalis, or of spermatocele, or of encysted hydrocele of the spermatic cord. I have never produced suppuration. I have never yet failed to effect a radical cure. I have operated in one instance upon five cysts of the cord (three on one side, two on the other), in a man of sixty five years, throwing in two and a half drachms, all told, of the pure acid, half a drachm in each cyst, keeping my patient in bed only two days, and curing him radically at one sitting. I have occasionally treated and cured a patient without sending him to bed at all, and I have not had any serious accident. I have occasionally seen considerable pain on the second day, with sharp inflammatory reaction and prompt re-accumulation of fluid, which I have considered it prudent to draw off with the aspirator; but this and a poultice has always relieved the inflammatory tension, and suppuration has never occurred, or any evidence of carbolic acid poisoning. I do not say that serious complication is impossible; but in various cases, in hospital and private practice, numbering more than fifty, I believe, although I have not kept strict account of the number, I never have had any serious accident or complication, and I think that great praise is due to Dr. Levis for introducing so valuable a remedy.

But here again I have to propose a method of operation which is the only one I have ever employed, and which seems to me to be simplicity itself. I do not use the cannula and long-nozzled syringe proposed by Dr. Levis.

The apparatus I employ is a glass syringe holding one hundred minims, having for its nozzle an ordinary hypodermic point, not the very smallest size. If the cyst is small this point is thrust into it and the clear contents of the cyst drawn out with the syringe. Then the latter is unscrewed from its point, rapidly and thoroughly washed, and promptly filled with the pure carbolic acid deliquesced with a little glycerine.

The syringe is now screwed again upon the point which has been left sticking in the cyst, and from thirty to sixty minims of the deliquesced acid thrown in. The point is now withdrawn and the whole operation terminated, with not much more trouble than it takes to give a hypodermic injection.

Generally, little or no pain is felt, no carbolic acid gets upon the scrotum or the operator's fingers, and the after-treatment is simply regulated according to the grade of inflammatory reaction produced. Sometimes there is no pain whatsoever during the entire course of cure, which (the cure) I have come to look upon as constant. I have operated in a hospital and my patient has walked away. I have at times operated in my office and sent the patient home; but I prefer not to do it. I have several times operated at home on very large hydroceles of the tunica vaginalis, and my patient has simply kept his room, not even gone to bed, and has gone about his business as usual in forty-eight hours. I have thus far always insisted upon this amount of confinement to the house.

When the hydrocele is large I modify the operative method as follows:

I first insert the hypodermic point and see that a drop of clear serum oozes from it. I now puncture the cyst at another point with a fine aspirating needle, empty the contents, and withdraw the aspirating needle. I then screw the glass syringe upon the hypodermic point first introduced and throw in the drachm of deliquesced acid, which appears to be all that is required to accomplish the cure.

Nothing is easier, no operation of minor surgery in my hands has been more satisfactory in its results.

The Dissemination of Small-pox.—In a bulletin from the State Board of Health of Maine, it is shown that there are eighty-six places in the province of Quebec known to have received the contagium of small-pox cases from the epidemic at Montreal.

REFLEX SYMPTOMS OF NASAL DISEASE.[1]

By HENRY SCHWEIG, M.D.,

THE tendency of late years to examine more critically into the causation of certain morbid phenomena, has resulted in a more thorough and efficient application of the various aids to diagnosis, as well as a better appreciation of the significance of existing pathological conditions in nasal disease.

I use the term "nasal disease" in its broadest sense, including in this category not only permanent structural changes, neoplasms, etc., but also those conditions, the existence of which can only be demonstrated under favorable circumstances and surroundings.

When we consider the extensive mucous surface directly continuous with the lining membrane of the nose, the many remote complications that may have their origin here find an explanation. The points of communication are many I may mention here the sphenoidal, ethmoidal, maxillary, and frontal sinuses, the lachrymal duct, the Eustachian tubes, the pharynx, mouth, œsophagus, larynx, etc. That these various tracts may serve as avenues for the extension of nasal diseases, and that nasal disturbances in their turn may cause remote effects by interfering with the proper functional activity of the contiguous parts, there can be no reasonable doubt.

Observations lately recorded by Hack, Bresgen, and others, make it evident that even parts having no apparent connection with, or relation to, the nose may be in sympathy with its various affections. The observations of Horace Green go far to show that, during the time when the laryngoscope was an unknown factor in the diagnosis of diseases of the upper air-passages, the possible connection between throat and pulmonary diseases was assumed to be more frequent than could be demonstrated.

Budd and Elsberg proved the frequent intimate relation between uterine and throat diseases, and their recorded observations show that rarely did one complication yield permanently, unless the other received its due share of attention. Chroback (1869), *Wiener Medizinische Presse*, calls attention to the respiratory neuroses accompanying some cases of retroflexion. Prosser James, in the London *Medical Times and Gazette* (1859), points out the apparent sympathy between the tonsils and the ovaries. The recorded cases of careful observers include as directly traceable to nasal diseases, dizziness, cough, dyspnœa, photophobia, frequent attacks of sneezing, hay fever (so called), loss of smell, toothache, facial and supra-orbital neuralgia, asthmatic attacks, spasm of adductors of the vocal bands, hemicrania, pharyngitis, laryngitis, swelling and redness of the nose, rhinitis, eczema of the upper lip, frontal headache, otitis, tinnitus, conjunctivitis, annoying lachrymation, disturbance of vision, etc. Hack mentions a case under his observation, in which a very marked œdema and redness of the wrist developed as a prompt result of cauterization of the nose for a hypertrophy of the tissue covering one of the inferior turbinated bones; and Elsberg (1870) calls attention to the frequent connection between throat diseases and dyspepsia

An endless array of cases showing cause and effect could be cited, and might serve to give color to many startling theories that have been advanced in regard to the subject before us; but calm judgment and a careful analysis often show that affections apparently directly reflex, may have been merely coincident with, and not due to, the nasal affection, and that even marked hypertrophic changes often fail to produce the characteristic symptoms supposed to follow in their wake. It is only by careful and unprejudiced observation, coupled with a tabulation of cases, that definite conclusions can be arrived at; and when individual observations agree in every particular with the observations of others, then only can deductions be drawn and facts established upon which a firm line of treatment can be based. The accuracy of examination and the ultimate proper diagnoses of cases is the all-important factor to which I desire to call special attention, for statistics become useless if one observer details the symptomatology of a case, and comparing it with other recorded cases finds, his own observations corroborated; while another perhaps, in precisely the same train of symptoms, examines his patient, and finds that appearances accepted as pathognomonic are conspicuously absent.

The too early acceptance of conclusions based on the first examination, however thorough this may be, is misleading, the causes operating to produce characteristic appearances being often absent. For example, the sudden enlargement of the surface over the turbinated bones, due to the inhalation of cold air or irritating vapors, will often readily subside on the inhalation of warmer or purer air; and cases of so-called anterior nasal hypertrophy, in which soft, yielding tumors of considerable size encroach on the lumen of the nasal passages, will, for some unknown cause (perhaps psychical), suddenly fail to present any of their characteristic appearances for a time; again becoming visible under predisposing causes.

The importance of carefully going over the whole field—that is, the successive examination of every accessible point, from the tip of the nose to the oro-pharynx, is strongly urged, and the rather superficial method of exploration, too often indulged in, where the first pathological factor that may present itself is accepted as the whole cause of an existing state, is to be strongly condemned.

We frequently meet with cases in which exist a number of pathological conditions, each one of which in itself would be sufficient to cause serious disturbance.

I recall the case of a gentleman who consulted me in September last, suffering from occasional nasal occlusion and, as he expressed it, a distressing "stuffy feeling" in the posterior portion of the nose. Patient stated that, a few months previous, he had consulted his physician in regard to the ailment, and a diagnosis of nasal polypus had been made, and verified by the removal of a mucous growth of considerable size. His symptoms, after removal, became rather worse than better, this being attributed to manipulation of the parts during operation. Applications of sedatives afforded only slight and passing relief. When patient consulted me I found no trace of polypus, and, in fact, nothing objective which would have warranted me in giving any opinion. Patient's statements, however, led me to believe that the erectile nasal tissue played an important part in determining his trouble, and subsequent examination verified this. Cauterization with the galvano-cautery effected a complete and speedy cure. Cases of deflected septum frequently exist with hypertrophy of the turbinated tissue on the opposite side. If we accept certain reflex phenomena as due to either one or the other of these conditions, and if only one be remedied, the other may still keep existing morbid phenomena active.

Nasal diseases causing reflex phenomena should be classed under four heads: First, neoplasms; second, deformities, either congenital or acquired; third, breach of surface; fourth, circulatory disturbances. I do not include syphilis.

The first three varieties have long been recognized as capable of affecting organs not immediately concerned in respiration, but the fourth has only recently received that attention which its great importance merits, and it is just this variety which requires the greatest diagnostic skill, and the clearest understanding of the main points in differential diagnosis. It should be determined, and that beyond a doubt, whether disturbed circulation exists

[1] Read before the Laryngological Section, New York Academy of Medicine, January 22, 1886.

merely on the surface—that is, whether we have before us a case of rhinitis pure and simple, or whether the underlying structures are involved, or perhaps both. Remedial agents differing materially in their effects are indicated in one or the other class of cases. In surface irritation the membrane is red, frequently tense, and comparatively non-compressible. The secretion of mucus is generally increased. The reflex phenomena that follow in the train of this class of cases are few in number, and their connection with the nasal complaint generally recognized. Deep circulatory changes, however, may exist with little or no modification of the secretory function of the mucous membrane, but with a train of accompanying symptoms as varied as they are interesting. Once recognized, there is perhaps no condition the treatment of which gives prompter or more brilliant results.

Rhinitis, pure and simple, requires only passing notice. The indications to be met here are, first, a thorough cleansing of the affected surface, and the application of that remedial agent which in the estimation of the operator may be deemed best.

Too much stress cannot be laid on the desirability of bringing the medicament selected in direct contact with the mucous membrane. It is not always an easy task to thoroughly remove the viscid or inspissated mucus covering the parts; and the negative results obtained in a proportion of cases are directly traceable to a superficial application made to the mucus covering the parts, and not to the *cleansed* surface. The recognition of the deeper circulatory disturbances—and I refer here mainly to the soft, yielding tumors marking the site of over-distended cavernous tissue—is frequently attended with much difficulty; but when the diagnosis is once fully established, the matter of therapy becomes clear.

I cannot give a better example of the effect of the over-distention of the cavernous sinuses than by detailing a case that came under my observation about one year since. Mr. J——, a pianist, aged twenty-two, consulted me in the winter of 1884. For about two years previous he had suffered from intermittent occlusion of both nasal passages, accompanied at the time of attacks by a profuse watery discharge, generally so copious as to materially interfere with his vocation. Sneezing at such times also became a prominent symptom, dyspnœa was more or less marked and violent, and hemicrania frequently compelled him to seek relief in small doses of morphia. Patient was of an exceedingly nervous temperament, and when I proposed to him to make a thorough examination of both nasal passages, he could only, after much persuasion, be induced to permit it. I discovered, on examination, hypertrophy of both inferior turbinated bones, the tissue on the right side touching the septum, an enlargement on the left side being almost as marked. Either enlargement could be readily made to disappear by gentle pressure with a flat instrument, but would promptly reappear as soon as pressure was relaxed. The mucous membrane itself did not participate in the disturbance, was normal in color, and not sensitive to the touch. Patient dated his trouble from a coryza which was slow to disappear, and which, at the time, was accompanied by a very high temperature and general disturbance. This patient exemplified in a marked degree the class of cases in which improper surgical interference is often productive of great harm, substituting for the original complication a condition almost as distressing as the one remedy.

I gather from the available literature that the tendency is, in dealing with enlargements like the one above mentioned, to use a broad flat burner, connected with a galvano-cautery battery, and to destroy the entire enlargement from the surface inward. This practice I cannot too strongly deprecate, as the enlargement is removed at the expense of impairment of the secreting function of the mucous membrane at the site of cauterization, the muciparous glands being destroyed. I have frequently seen large cicatricial patches in the nose, harsh in appearance, and covered with scales of dry mucus. Inquiry elicited the information that cauterization had been practised for the removal of hypertrophied tissue.

Large flat burners should, in my opinion, be condemned. I am personally responsible for one form of flat burner which I no longer use. Large hypertrophies can be more effectually removed, and the integrity of the nasal mucous membrane not interfered with, by another method, much simpler, less painful, and more rapid. I refer to the employment of a slender platinum wire point (connected with the galvano-cautery battery), which by changing its position can be made to destroy successively the various portions of any growth without materially enlarging the original point of entrance, which should generally be at the base, and anteriorly. Growths thus destroyed collapse in a few days, and leave no trace of their former existence, except perhaps a round cicatricial point about the size of the head of a pin. The mucous surface has been kept intact, and secretes as if no cauterization had been practised.

It is not my purpose to call attention to any new phenomena, or to evolve any theories regarding the interesting subject before us, but I prefer to content myself by strengthening existing material, and suggesting slight modifications in methods already known. That much mischief is done by the indiscriminate use in the nose of various destructive agents where reflex nasal phenomena manifest themselves, and that many an operative interference could have been dispensed with, we well know; but that also many conditions which we now refer to nasal disease, could in the past have been remedied had their cause been recognized, will not be disputed, and I think that any stimulus that will further closer observation in this field, not alone in the matter of cause and effect, but also in therapy, should be looked upon as a step in the right direction.

The recital on my part of numerous cases would not add much to our knowledge, but careful investigation, correct data, and above all therapeutic measures based upon correct diagnosis, will add much toward bringing the matter of rhino-therapeutics to the level of one of the exact sciences.

A NEW METHOD OF TREATING CLEFT PALATE.

By GEORGE ARTHUR, M.D.,

DEMONSTRATOR OF OPERATIVE SURGERY IN THE NEW YORK POLYCLINIC.

THIS method is adapted to those cases only in which the cleft involves the hard palate.

Although a reasonable degree of success has been obtained by the purely mechanical treatment of cleft palate, it has been, in almost every case, at the cost of long and persistent practice on the part of the patient, requiring an amount of intelligence and perseverance that are not always found in the subjects of the treatment.

Unless the artificial velum, when in position, permanently abuts against the posterior wall of the pharynx, which is not desirable, and even if it were, is likely to give rise to irritation and ulceration of the pharyngeal wall, a vacant space must be left between the posterior free border of the instrument and the back of the pharynx. Thus the superior constrictor muscles can learn to close, only after long practice, and in the most favorable cases, since they must be trained to supplement the defective palatine muscles in closing the upper part of the pharynx, by meeting and grasping the posterior margin of the artificial velum.

In many cases that are considered successful the characteristic unpleasant nasal timbre of the voice is not corrected, although tolerably clear articulation has been secured. This defect is due to the imperfect adaptation of the pharyngeal constrictors to the posterior border of the instrument, leaving a chink by which air can pass

through the nose, instead of being diverted completely into the mouth, as would occur with the normal palate.

Good results have also been obtained by the surgical treatment of cleft palate alone, especially when it has been done in early infancy and the defect is confined to the soft palate. In the greater proportion of cases, however, in which the cleft is extensive, necessitating the operation of uranoplasty, the results are by no means perfect; indeed, it is unusual, when the operation is done after infancy, that ever great improvement in speech is obtained.

The probable reason that the operations of staphylorraphy and uranoplasty do not furnish better results is, no doubt, because the velum is left too short and rigid to play its proper part in closing the pharynx, and effectually diverting the column of air through the mouth.

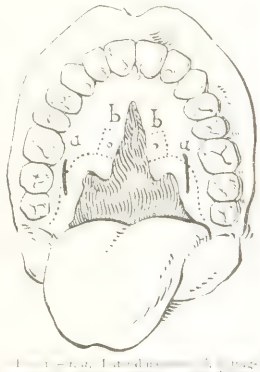
On the whole, the mechanical treatment seems so far to have been rather more successful than the surgical.

The great defect in the instruments heretofore relied on is that the mucles that normally raise the velum palati are not used at all. The tensors and levators of the palate, deprived of their normal insertions in the middle line of the velum and uvula, hang uselessly on either side of the artificial velum, and take no part in raising and otherwise manipulating it; hence the necessity for the increased and unusual action of the pharyngeal constrictors.

If the elevator muscles of the natural could be made to act upon the artificial palate, so as to make it imitate all the movements of the perfect normal velum, and lift its free edge upward and backward into contact with the back of the pharynx where the constrictors could easily and without unusual or special action grasp it, much better articulation would result, and this desideratum can be secured by the following method, in which the surgical and mechanical methods are combined, and the defects of both avoided:

The first step in the treatment is to unite the two halves of the uvula and soft palate as completely as possible.

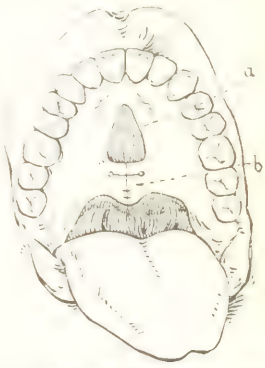
This may be done by freshening their edges and securing them together with sutures—preferably the perforated-shot suture. If the cleft is too wide for this to be done without undue tension of the parts, small portions of the posterior and internal borders of the free edges of the palatine processes, large enough only to furnish secure support for a silver wire to be passed through perforations drilled through their centres for the purpose, may be cut off with a fine, sharp chisel under the mucous membrane, which should be completely separated from their inferior surfaces with the periosteum, or fractured off after suitable guiding perforations have been made, as shown in Fig. 1. These fragments should be brought close enough together with a strong wire, to relieve the wound of tension.



If the above proceeding fails to relieve all tension on the wound, incisions, partly or entirely, severing the tensors and levators, as recommended by Langenbeck, may be made (Fig. 1, *a*, *a*), but it is advisable to avoid all cutting of these muscles, if possible, in order to preserve them intact for their future function.

It may also be necessary to divide the palato-glossi and palato-pharyngei muscles with scissors; but with the above precautions it is not probable that the healing together of the velum will be endangered, or even retarded.

When the wound has healed the condition of the parts will be as shown in Fig. 2, furnishing a soft palate, short and incomplete, but with points d'appui for the palate muscles that permit them to perform their function of manipulating what palate there is, as in the normal condition, instead of merely dragging the separated halves further asunder when they contract, as was the case before they were united.

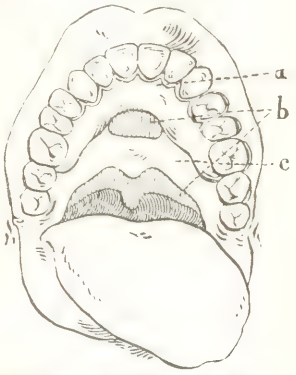


No attempt is made to close the hard palate, the object of the surgical part of the treatment being merely to remedy the defect of the velum and uvula. Indeed, it is rather an advantage to have a large opening in the hard palate, and this should be borne in mind when cutting or breaking off the fragments of bone as before described.

The parts are now ready for the mechanical appliance, which is to lengthen and otherwise supplement the deficiencies of the newly made natural velum.

A plate of suitable material—gold, silver, or hard rubber—is now fitted to the hard palate, extending nearly to its posterior margin, but not quite to the posterior end of the cleft. This plate must fit very accurately to the margins of the cleft, and slightly overlap them.

To the upper surface of this rigid plate is attached a flexible soft-rubber velum, which rests upon the natural



velum, and is shaped in moulds made from impressions and casts of the natural parts so as to fit them exactly, and imitating as closely as possible in contour the normal soft palate. This is attached to the artificial hard palate only in the median line from the anterior angle of the cleft to the posterior edge (of the artificial hard palate), filling up, when in position, that part of the cleft, or now, more properly, aperture in the natural palate which is left uncovered by the rigid plate, and continued beyond the free border of the natural velum as far as may be necessary to compensate for its defective length.

The portions of the flexible-rubber palate that are attached to the plate in the anterior part of the mouth, and that fill up the posterior part of the aperture in the palate, which it must do completely and perfectly, may be thick

and substantial, while the continued portion of it that rests upon the natural velum, should be light and thin, only sufficient thickness being necessary to enable it to recover its form when released from pressure, and to maintain it when the muscles that move it are passive.

The instrument is placed in position by doubling the flexible-rubber portion upward with a pair of long, light dentists' gold-pliers, and thrusting it upward and backward through the aperture left in the palate. The pliers are now withdrawn, and the hard-rubber plate is placed in position, so that the tooth-clasps, or atmospheric chamber, by which it is held, will take hold. When this is done, the flexible-rubber velum will have unfolded and adapted itself to the upper surface of the natural velum, as in Figs. 3, 4, and 5.

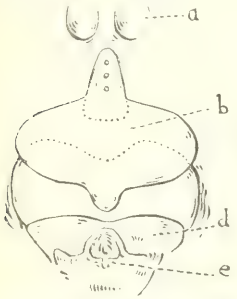


FIG. 4.—Posterior View of Fig. 3. *a*, Posterior nares; *b*, artificial velum; *d*, fibers of tongue; *e*, epiglottis.

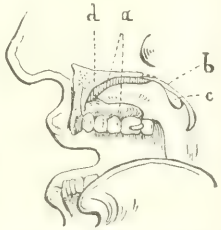

FIG. 5.—Lateral View of Fig. 3. *a*, Hard-rubber plate; *b*, soft-rubber velum; *c*, natural velum; *d*, natural hard palate, which in the figure extends too far posteriorly.

The plate and artificial velum are to be vulcanized in moulds made from casts of the natural parts as described by Dr. Norman W. Kingsley[1] and Mr. Coles.[2]

The impression of the upper surface of the natural velum and the adjacent soft parts, from which the casts and moulds are made, should be taken while the soft palate is passive and pendulous, or even depressed somewhat below the normal, so that the superjacent artificial soft-rubber velum shall tend to press gently upon it in every position, and closely follow its movements.

By this method an artificial palate is obtained which is under perfect control of the palatine muscles, and which is light and flexible enough to adapt itself to the changes in form of the tongue, pharynx, and palate, in all the movements of articulation, deglutition, and respiration.

36 WEST THIRTY-THIRD STREET.

EPILEPSY OCCURRING WITH OPTIC NEURITIS.—M. Galezowski relates the case of a young man who had had one eye destroyed by an accident while shooting. The anterior hemisphere had been removed, leaving the stump of the eye in its socket. Six years later the vision in the sound eye became poor, examination showed the presence of neuro-retinitis, and at the same time the patient began to suffer from epileptic seizures. The stump of the wounded eye was removed, and immediately the attacks of epilepsy ceased and the sight in the opposite eye began to improve. Taking into consideration the results of the operation and the connective-tissue degeneration and nerve atrophy found on microscopical examination of the stump, M. Galezowski assumed that the neuro-retinitis, and the cerebral trouble accompanying it, were due to a sympathetic reflex action. There was, he thought, in the meninges, or in some part of the brain, a lesion similar to that revealed by the ophthalmoscope in the engorged papilla of the optic nerve. —*Revue Médicale*, January 2, 1886.

A CASE OF "DAYMARE."

BY T. M. HOLMES, M.D.,

ROME, GA.

MRS. ——, the wife of a clergyman, became a resident of this city in the summer of 1883, and soon thereafter she consulted me with regard to her health. I found her to be a very intelligent lady of about thirty years of age, a blonde, rather below the medium size, and of pleasant face, but bearing marks of anxiety, as one who was a subject of much mental or physical suffering. I soon discovered that she was of an exceedingly nervous temperament, and she informed me that for many years she had had frequent and very severe attacks of catalepsy. When a girl she had been troubled with similar attacks of a milder nature, but after her marriage they became more frequent and more intense, and seemed to be aggravated in an increasing ratio by each succeeding period of gestation. At this time she was the mother of five children, the oldest being about fourteen and the youngest three years of age.

She had been under the treatment of several prominent physicians in South Carolina, whence she had recently come, and had tested to the fullest extent every therapeutic agent usually employed in neurotic troubles. Nothing, she thought, had ever done her the least particle of good in the way of keeping off the attacks; and during the seizures themselves the hypodermic use of morphia was the only agent of relief, with any degree of permanency, that she had ever used. This mode of administration was very necessary, because of extreme nausea immediately following its internal administration, and the consequent failure to take effect.

I was soon called to see her in one of these distressing seizures. It was most severe and obstinate. She felt it coming on and had taken to her bed. On my arrival, I found her in the recumbent position, her hands clenched in each other as tightly as if held in a vise, and could not be separated. Her feet and legs were drawn backward, the former resting on their palmar surface. The face was like that of a woman straining in labor, with the exception of color, for she was quite pale, as in a nervous rigor. She presented a spectacle most pitiable to look upon. Her mind, as usual during these attacks, was perfectly clear, being cognizant of all that was going on around her. The pupils and respiration were perfectly normal, as was also the pulse, though the latter was hard to detect, because of the rigidity of the radial tendons. Her teeth were firmly clenched, so that it was out of the question to give medicine by the mouth, to say nothing of the rebellious stomach. I therefore proceeded to relieve her condition by the administration of chloroform, until the muscular contractility was completely overcome. This left her fingers quite white where they had pressed against each other, and purple at their extremities. This relief did not last long, for in a few moments the same symptoms recurred, and did not entirely disappear until the patient was thoroughly under the influence of morphia. Soon after complete relaxation was obtained she vomited. This was usual with her after these spells.

These attacks recurred from time to time, but she was not always in a position to secure recumbency. They were liable to come on while she was walking the streets, or the floor attending her household duties; or while sitting with her little ones around her, and whatever position she might be occupying, in that she would usually be immovably "fixed." However, if her limbs happened to be in a position in which some object was holding them, and that object were removed, they would immediately assume a position of extreme flexion.

On one occasion I was hurriedly summoned to see her, and on arriving found her walking the floor at a very rapid pace. Her hands were raised before her, and she was slinging them as if they were covered with a thousand stinging insects. She was evidently in great agony. With difficulty I administered hypodermatically one-half

grain of morphia, and entire ease and repose soon followed. On another occasion she felt an attack coming on while in church, and immediately left the building. On reaching the street it seized her, and she was forced to cling to the fence to prevent falling. There she stood, unable to move, being all the while in mental torture for fear the congregation would be dismissed and behold her in this very embarrassing position. From this humiliation, however, she was rescued by the appearance of a friend, who suspected the cause of her departure.

The timely administration of morphia would always keep off an impending attack. During these attacks there was never insensibility to pain or the touch. She was simply unable to speak or move. The pain was usually not great, and seemed to be solely the result of muscular contraction.

Diagnosis.—In speaking to her of her trouble, I retained the name to which she was accustomed—that of catalepsy; but while it was extremely cataleptiform, it was by no means the "catalepsia vera" of Ziemssen, Da Costa, Flint, and others. It was like a case reported by Sir Thomas Watson, which this eminent physician denominated "daymare." In the case described by him, there was total inability to move or speak; yet the patient was perfectly cognizant of everything about her. Now, according to Ziemssen, "catalepsia vera" has two pathognomonic symptoms—the "stiffening of the muscles," and the so-called "flexibilitas ceria"—the susceptibility to passive motion. That is to say, that the muscular tension may be sufficiently overcome by an attendant to admit of a change in the position of the limbs, in which position they will be "fixed" as before. This is impossible in "daymare," since there is not a moment's relaxation of muscles. There is also in catalepsy anæsthesia, analgesia, and sometimes suspension of consciousness, but none of these symptoms exist in "daymare."

Pathology.—Sir Thomas thought that in his case the seat of disease was the cerebral blood-vessels. If this were true, "daymare," as De Costa has suggested, would be a very grave affection; but in this opinion of the pathology of the disease I do not concur. At least I am quite sure that such was not the case with the subject of this article. From the history and symptomatology of this case I was led to believe that the origin of the trouble was in the uterus. To ascertain the truth of this, a specular examination was necessary, in which procedure I invited the celebrated Dr. Robert Battey to assist me. We found, as I had anticipated, a fearfully ulcerated and congested os. This was the "open sesame" to the whole trouble.

Prognosis and treatment.—We told our patient that by care on her part in abstaining from overwork and worry, which generally promoted the attacks, and by a persistence in our course of treatment, she might entirely recover. This treatment would consist of an application of iodized phenol once a week to the os and endometrium. In this way we hoped to relieve the congestion, allay the inflammation, obtund the sensibility, and so alter and tone up the diseased mucous membrane and relaxed muscular tissue as to restore the parts to their normal condition.

This treatment was persisted in for several months with but very little improvement, the seizures coming on at irregular intervals. The uterus was several times found to be so retroflexed that it was almost impossible to make the applications. Believing, therefore, that support would benefit the uterus while in this diseased and atonic condition, I supplemented our treatment with Tallíofera's cotton tampon, saturated with his usual preparation of iodoform, balsam of tolu, and glycerine. This gave the uterus such support that the patient experienced immediate relief, as if a load had been removed from the inferior pelvis. From this date she began to improve rapidly, both as to the frequency and severity of the attacks, and her general health was in a short while much improved. Her menstrual periods failed to appear some weeks before the institution of the tamponing, but I did not think it possible that conception could have taken place under such circumstances. Especially did I think it improbable when she informed me that they had failed to appear once before without developing anything more than an aggravation of her trouble. However, in this instance, we were destined to be undeceived. Her husband was called to another field of labor and in due season she gave birth to her sixth child. Since their removal I have been unable to follow up this most interesting case.

Clinical Department.

OPERATIVE TREATMENT OF CHRONIC VESICAL CATARRH.

In an elaborate paper read before the Dane County Medical Society, on September 1, 1885, Dr. A. F. Jonas, of Madison, Wis., argues with much force in support of the operative treatment of this obstinate and troublesome affection. A great many drugs have been recommended from time to time in the treatment of chronic catarrh of the bladder, some even being extolled by enthusiastic advocates as veritable specifics, but none has maintained its ground as a remedy of real value. The balsams, which deserve to rank among the first in point of efficacy, must often be discontinued before the desired result has been obtained, by reason of the disturbance to the digestive functions which they excite. Local treatment was first instituted, the writer says, by French surgeons, and the excellent results thus obtained demonstrated the importance of topical applications to the bladder. But, although this method was often successful, there were, nevertheless, numerous failures, due in many cases to the fact that solutions of sufficient strength to destroy the micro-organisms would be dangerous, either from their local action upon the vesical mucous membrane or from absorption. This method also demands the frequent passage of a catheter, with all its attendant dangers; and, furthermore, it is impossible to reach the whole inner surface of the bladder, since the mucous membrane lies in folds around the eye of the catheter, and the fluid passes out again after having moistened only the small portion of the lining membrane of the bladder which happens to lie in contact with the end of the catheter. Attempts to introduce a sufficient quantity of fluid to distend the bladder and thus secure contact of the solution with every portion of the mucous membrane, usually cause such severe pain as to necessitate their discontinuance. The conditions here existing the writer compares to a wound with many pockets and recesses, in which the secretions accumulate and decompose. The treatment of such a wound is perfect drainage, and the same principle should be applied to the management of chronic vesical catarrh. An incision should be made into the bladder and a drainage-tube inserted. Dr. Jonas states that Bouchardat, in 1803, was the first to treat this affection by incision, but that Willard Parker was the first to publish and advocate the method of treatment. The author reports a case in which he employed drainage with success. The patient, a man sixty years of age, had suffered from inflammation of the bladder for three years, and when coming under observation was greatly prostrated, and had a countenance indicative of great suffering. An attempt was made to irrigate the bladder, but it caused severe pain and had no effect upon the disease. Upon consultation with Drs. Coolige and Gapen, it was decided to operate. A median incision one inch in length was made in the perineum, and the membranous portion of the urethra then opened with a lithotomy staff for a guide. After some difficulty, the prostatic portion was dilated with

the finger, and a rubber tube with well-rounded edges was passed into the bladder after the viscus had been carefully cleansed. The perineal wound was packed with iodoform gauze, and the tube was passed over the side of the bed, its free extremity lying in a vessel containing a solution of carbolic acid. With the exception of a temporary rise of temperature, accompanied with delirium, on the sixth day, the progress of the case was favorable, and the patient made an excellent recovery. As regards the method to be employed, the writer prefers a median incision. The incision is not carried into the bladder, but the tube is passed through the prostatic portion of the urethra, thereby answering a good purpose in overcoming the spasm of the sphincter which is often so prominent a symptom. The tube may be removed when the urine has become acid in reaction, and the other symptoms have subsided. The operation, of course, should be reserved for those cases in which other measures have been proven by trial to be ineffectual.

THE NECESSITY OF REVACCINATION.

THE following cases illustrate well the wisdom of frequent revaccination, at least as often as the liability of exposure to small-pox occurs. Dr. E. A. Cobleigh, of Athens, Tenn., referring to some recent instances reported in THE MEDICAL RECORD, states that he has observed three cases in his own family in which the protection afforded by vaccination was lost after comparatively brief periods. He writes: "My father was vaccinated successfully in his fifteenth year, and had a large and typical cicatrix. At varying intervals thereafter he was tested by revaccination, and when I entered upon the practice of medicine (as it is my invariable custom to revaccinate all the members of my family whenever variola exists in the vicinity) I also tested him frequently, and without results until his fifty-sixth year, when an atypical and abortive vesicle followed my puncture. I repeated the test, a few weeks later, twice, and failed. When he was fifty-eight years old I had occasion to try him again, and it took as regularly and thoroughly as I ever saw it on an infant. I repeated the experiment on father several times during the next two years (till his death) with negative results.

"The next case I have to report is myself. When an infant I was successfully vaccinated. At seven years of age I had varioloid. After entering the profession I put scores of samples of vaccine lymph under my cuticle, and treated variola with impunity. This continued for eight or nine years when, much to my surprise, one of the vaccinations 'took' on me to perfection, and I had a large, typical vesicle, and a raging fever, the arm necessitating a sling for several days. My rule has long been to *repeat* my vaccinations as soon as the first has run its course, until saturation of the system is shown by the efforts failing. I did so in my own case, and have repeated the operation several times at intervals since, with no effect.

"The third case is a son. When he was a baby in arms small pox came pretty close to us, and I vaccinated him with humanized virus, getting three very nice vesicles. These ran their course, and I repeated the effort, but without effect. A year later I had occasion to once more test this same son's liability to take the disease, and again had three vesicles. Repetition at short intervals now also failed; but a year later, or thereabout, the same thing was gone through with, and this occurred for four years four several times. Now the susceptibillty ceased for four years, and then it again 'took.' Again, four or five years later he was successfully inoculated, since which time he has seemed thoroughly protected and proof against any further efforts. Of my other two children only one vaccination in infancy has been necessary for protection."

Dr. F. E. Porter, of Auburndale, Mass., reports the case of a man, sixty-five years of age, who had confluent small-pox in 1850, and still bears the marks of it on his face. He was vaccinated on December 30th with fresh bovine virus, and on January 8th Dr. Porter writes: "He carries to-day the typical vesicular circle and red areola, as in primary vaccination. Constitutional symptoms are now well marked, and the man is evidently going to have all the conditions, subjective and objective, that belong to vaccinia. The cases that I have thus far seen reported were, like the above, in persons who had had the disease many years before, and vaccination, as previously performed, had been with humanized virus. As far as it goes, this would seem to confirm what Dr. S. C. Martin said at a recent meeting of the Suffolk District Medical Society, to the effect that bovine virus induces a distinct disease which protects the system from an invasion of small-pox, while humanized virus does not do so."

Progress of Medical Science.

IODOFORM INJECTIONS IN KNEE-JOINT DISEASE.—Dr. Piltz reports the case of a woman, fifty-eight years old, who had suffered from pain and swelling of the knee for about a year. In spite of active treatment the disease progressed steadily until the patient's health began to suffer. An exploratory puncture showed the presence of thin, flocculent pus. The author determined, before resorting to incision and drainage, to try the method of iodoform injection recommended by Mikulicz in the treatment of cold abscesses. The joint was punctured with a trocar and about a pint of pus removed, and it was then thoroughly washed out with a three per cent. solution of carbolic acid. After this, about two ounces of a ten per cent. iodoform glycerine emulsion were injected and an antiseptic dressing applied. No elevation of temperature followed the operation. The general and local effects of the injection were described as wonderful. The pain yielded at once, and merely a slight burning was felt in the joint. The patient slept well that night for the first time in many weeks. At the end of six days a little pus had reaccumulated in the joint. The operation was repeated, a smaller quantity of the emulsion being injected. After this no more pus was found and the patient continued to improve, regaining the use of the knee and increasing in weight. The author believes that this method might be advantageously employed in all joint diseases of this sort in which there is no lesion of the osseous structures.—*Allgemeine Medicinische Central Zeitung*, No. 94, 1885.

THE HERPETIC DISEASES.—Dr. Luton writes in the *Bulletin Général de Thérapeutique*, of December 15, 1885, upon the treatment of herpes, pneumonia, and croup, which he regards as diseases belonging to the same category and amenable to the same therapeutic measures. The treatment consists in the administration of arsenic, preferably the double arseniate of sodium and potassium. This is given either by the mouth or hypodermatically. A solution is made of two-fifths grain in four ounces of water, of which a tablespoonful is given every two hours. When used hypodermatically, fifteen minims of a one per cent. solution are injected three times a day.

IMPERFORATE HYMEN.—At a meeting of the Surgical Society of Paris (*Gazette des Hôpitaux*, December 12, 1885), M. Segond related the case of a young woman, twenty years of age, who had apparently never menstruated, but who suffered periodically from severe abdominal pains. Various emmenagogues had been given, with the effect of merely increasing the difficulty. On examination, M. Segond found a large fluctuating tumor extending three fingers' breadth above the umbilicus. The hymen was found completely occluding the vagina, and greatly distended. The uterus could be felt of nor-

mal size. The patient was anæsthetized and a crucial incision was made in the hymen, permitting the retained menstrual fluid to drain away slowly. After the complete evacuation of the tumor, which required about forty-five minutes, a drainage-tube was inserted and the vagina washed out with a 1 to 2,000 sublimate solution. An antiseptic dressing was then applied. After a few days there was a slight stomatitis, requiring the substitution of carbolized injections for the sublimate solution. The patient experienced no untoward symptoms, and has subsequently menstruated regularly and normally.

Cold Bandaging of the Leg in Insomnia.—Dr. von Gellhorn has found the following plan very useful in inducing sleep in persons who suffer from insomnia. A piece of calico, about eighteen inches wide and two and three-quarters yards long, is rolled up like a bandage, and a third of it wrung out in cold water. The leg is then bandaged with this, the wet portions being carefully covered by several layers of the dry part, as well as by a layer of gutta-percha tissue, and a stocking drawn on over the whole. This causes dilatation of the vessels of the leg, thus diminishing the blood in the head and producing sleep. It has been found by Winternitz that the temperature in the external auditory meatus begins to fall a quarter of an hour after the application of the bandage, and the normal is again reached for from one and a half to two hours afterward. Gellhorn has employed this means of procuring sleep for several years, and finds it especially useful in cases where there is congestion of the cerebral vessels. Sometimes he has found it necessary to reapply the bandage every three or four hours, as it dried.

The Treatment of Winter-Cough by Pure Terebene.—During the last five years Dr. William Murrell has employed a method of treating winter-cough for which he claims excellent results. His experience extends to one hundred and fourteen cases. He says (*The British Medical Journal*, December 12, 1885) they were all treated with pure terebene, a substance prepared by the action of sulphuric acid on oil of turpentine. It is an agreeable remedy, being a clear, colorless liquid, with an odor like that of fresh sawn pine-wood. It will not mix with water, but, as the dose is small, it can readily be given on sugar. It is not the same as the patent medicine sold under the name of "terebene." One of the great advantages of pure terebene is that it is not a bulky medicine. An ounce bottle, carried in the pocket, will last for days, and is always ready for use. It is best to begin with five or six drops on sugar every four hours, and gradually to increase the dose to twenty minims. This is, for most people, the maximum quantity, but the drug has little or no toxic action, and one patient was so enraptured with his remedy that he insisted on taking a teaspoonful every four hours for a week. The only disadvantage Dr. Murrell has ever noticed from its employment is that it gives a peculiar and characteristic odor to the urine, a circumstance which patients never fail to mention. When used as a spray, from one to two ounces should be diffused and inhaled every week. In some instances he has tried giving it mixed with an equal quantity of olive-oil flavored with oil of peppermint. In twenty-five cases he gave the terebene in the form of an emulsion, made by mixing it with a little tragacanth powder, adding water and shaking well. Each ounce of the emulsion contained a drachm of the terebene, and it was usually given in half-ounce doses four times a day. The results were excellent, but not better than with the simple terebene itself, and he saw no reason for continuing the use of a more expensive preparation. In every case of winter-cough in which the terebene-spray was used systematically there was a marked improvement. In many instances it was noticed almost immediately; but in other cases, especially the very chronic ones, the patient had to continue using his remedy for some weeks. Even when there was marked emphysema, with little movement of the chest-walls, some benefit was experienced. He treated eighteen cases of phthisis by the same method, and the results were certainly most encouraging. It did most good when there was old consolidation, when no active mischief was in progress, and especially when there was no elevation of temperature. He has also used it as a dry antiseptic inhalation on the cotton-wool of a respirator in phthisis, and has been much pleased with the results. In one case, that of a young lady, the respirator was worn almost continuously night and day for nine months; and the right lung, which was breaking down, cleared up, the temperature becoming normal and the cough and other symptoms subsiding. He has no doubt that pure terebene would be useful in checking hemorrhage from the lungs, but on that point he has no experience. Many sufferers from winter-cough also complain of acidity and flatulence. The author soon found that the internal administration of pure terebene was an excellent remedy for this combination of symptoms. It checks the formation of flatus so quickly, and is so efficacious in expelling any that may remain in the stomach or intestines, that he constantly employs it in cases of dyspepsia when flatulence is a prominent symptom. Patients like it, and often continue taking it for months or years. It acts as an antiseptic, probably, in much the same way as glycerine, oil of cajeput, and oil of eucalyptus. Pure terebene is of such value in winter-cough that Dr. Murrell rarely experiences the necessity of resorting to other remedies.

Gelseminum Habit.—Dr. H. C. Caldwell (*Medical and Surgical Herald*) reports the following case: The subject was twenty-four years of age at the time the writer first met him. He was robust, had lived a life well divided between work on the farm, study, and rational recreations. Mentally he was of that type we style well balanced. He was, therefore, not such a person as we would expect to see become the victim of a habit. He contracted chills, rheumatism supervened, and he refused the frequent offers made him of chloral hydrate and morphia. His father had been addicted to the opium habit, and the son grew up with a horror of the very name of opium. In an attack of more than usual severity he took a large dose of fluid extract of gelseminum. Relief followed. The next day a repetition of the paroxysm called for a repetition of the dose. As with all quieting agents, the dose must be augmented, and during the year this increase was not very great. One hot night, in great agony, the sufferer took a very large dose and lay stupid until noon the next day. The experiences he had were, as he said, "wonderfully pleasant." Now the habit became fixed. The victim grew to using as much as a fluid ounce of the extract at one dose! What would once have produced death was now only a gentle palliative. Still the dose must be increased. He became pale, emaciated, listless, and, at times, strangely uneasy. He became the prey of strange terrors, and was subjected to some hallucinations of the senses. Looking fixedly at any distant object, he could discern all the colors of the spectrum; then darkness followed, and then a number of faint rays of light would precede the complete return of vision. His hearing became singularly acute. He was apparently regardless of what was passing; still, he could detect whispers uttered many yards away. Nothing could induce him to give up his darling drug. Seeing how the matter distressed his friends, he went away. During his stay of a year in Canada he increased the dose daily. He returned far more feeble, and at times seemed positively idiotic. He fancied ghosts were around him; he could hear the whispers of leering demons, and in his better moments saw the wings of angels hovering around his bed. After a year more of this strange habit, he sunk into a condition of hopeless idiocy, and died in the stupor induced by his idolized drug. The relatives of the unfortunate man never took care to prevent his obtaining the drug.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 20, 1886.

CHARITY REFORM IN LONDON.

IT would seem from recent statements in some of the London journals that discussion had begun in earnest concerning the reformation of medical charity, and that our transatlantic brethren were somewhat behind ourselves in actual progress made in this laudable direction. We are rather surprised to learn from a London letter to one of our cotemporaries that "an association of gentlemen has been formed to establish provident dispensaries in various parts of London, to which the poor are to subscribe so much a month or week, for themselves or families, so that they may receive medical relief, if necessary, at their own homes, in time of sickness." The fear is hazarded that "POSSIBLY some men who are in a position to pay a family doctor will subscribe to these dispensaries in order to avoid a doctor's bill."

Presumably human nature is alike in all countries, and we can assure these gentlemen that "certainly," and not "possibly," is the word to be used in this connection. Here, in New York, this plan has been tried. Its glaring inconsistencies, as evidenced at one particular institution, we have already pointed out. Weighed in the balances of justice to the profession, it has been found most lamentably wanting. We would advise our London friends to leave off before they begin. The experience of the last few years here in our midst warrants us in giving this advice.

It is somewhat interesting to notice a plan proposed in London to restrict the abuse of charity by the large hospitals. It is suggested that no patient should be treated in them whose credentials have not previously been passed upon by some dispensary. "It is proposed to affiliate several dispensaries to each large hospital, and practically to transfer the out-patient departments of the hospitals to the dispensaries."

We have been waiting for some time for a report from the committee appointed at the meeting held a few months ago at the Academy of Medicine, under the auspices of the Charity Organization Society. We hailed this step as a long-needed measure, and characterized it as the first-fruits of charity reform. We trust this committee is pushing this work vigorously. The time is ripe. Never before was so much interest manifested, both among and outside of the profession, concerning this question, and this interest must be kept up to the working point. A report merely of progress would be welcomed.

No close observer of human nature will ever expect that the world will become an Utopia, either in the dispensation or the acceptance of charity. The approximate toward this ideal is, however, our bounden duty. And this duty comes home to the dispensary physician as well as to the manager. To make one's dispensary service a field from which such cases as are suitable can be "run in" to one's office practice (and all who can pay anything are generally regarded as suitable cases), is not right. It is clearly a violation of those principles on which dispensaries are, ostensibly at least, managed. If the patients can pay anything, it should go to the dispensary treasury and not to the physician's purse. He "gives his services"—at least he says he does. Let the gift be in deed as well as in name. Unless it is so, a dispensary position becomes a place of money-making rather than a place for clinical study, pure and simple.

It is true that many among the working classes are able to pay sometimes and not at others; and as to their ability in this direction at any given time we have to take their word. Discretion must be exercised in managing such people, else we may pauperize them by a too hasty yielding to their importunities without looking with sufficient care into their circumstances.

THE YELLOW FEVER INOCULATION HUMBUG.

WE find that the evidence in favor of Dr. Domingos Freire's prophylactic inoculations against yellow fever is very slight, and that the probability is that we have again another inoculation humbug.

The New Orleans *Medical and Surgical Journal* has undertaken a vigorous crusade against Freire, and it states that "when we had fairly and honestly gone through the 650-page book of Freire and had found therein no evidence of the truth of his declarations, we regarded it as idle to think of investigating him in Brazil, and we felt that our friends, Dr. Holt and others, had gone into this commission-project without having made a critical examination of the scientific value of Freire's statements."

Our contemporary recalls the fate of two previous claims made for a prophylactic virus against yellow fever. One, made by Drs. Masuata and Fraschieri. They claimed that they could protect against yellow fever by the inoculation of "rocio," or dew, and they requested an investigation of their methods. Two members of the Havana Academy of Sciences reviewed and tested the experiments. The substance used was not a natural dew, but artificial, obtained by the condensation of the vapor of water contained in the atmosphere of the closed room of a yellow fever patient, collected on the surface of bottles. In one experiment made by them distilled water yielded "more remarkable results" than inoculation with "rocio." And yet this "rocio" had been much vaunted as a prophylactic against yellow fever—with just as much foundation, we believe, as the method of Freire.

Again, in 1854, a Dr. William Lambert de Humboldt, who claimed to be a nephew of the great Alexander Humboldt, notified the Captain-General of Cuba of his discovery of a sure means of preventing yellow fever, by the inoculation of the venom of an unspecified Mexican

snake. So much excitement was caused by his announcement that the Spanish Government appointed a commission to study the subject, and to test the experiments of Humboldt himself, and a French commission went to Havana from Martinique. "Two thousand four hundred and seventy-seven persons were inoculated from December 18, 1854, to June 28, 1855." No good results were obtained.

It is quite time that the medical profession should take a decided stand in protest against the methods adopted by these quackish claimants for notoriety. Medicine is discredited by the continual eruption of these El Mahdis of inoculative prophylaxis. It has been doubted whether it was wise to urge upon our National Government the appointment of a commission to investigate the claims of Dr. Freire and others. We have not opposed the project since such commissions sometimes learn facts of interest even if they discover no specific. We learn that the House Committee has reported, or will report, in favor of appointing a commission to visit Mexico, Central America, and Brazil, for the purpose of investigating the methods of prophylactic inoculation practised in those countries.

THE FEE QUESTION.

THEORETICALLY the physician, like the clergyman, is a philanthropist, and is actuated in the practice of his profession solely by the desire of doing good to his fellow-man, and possibly also by his love of science for science' sake. But candor compels us to assert that in neither case is theory strictly in accord with fact. Here and there may be found a physician or a clergyman who really seems to have a vocation for his calling, and to engage in it simply by reason of his devotion to his profession or of his love for his fellows, seeking for no pecuniary reward beyond what is necessary for his actual needs. But this class is not a large one, and, as a rule, the minister takes the church that offers him the largest salary, and the physician charges as high a fee as the circumstances of his patient, or the nature of the services rendered, will warrant. These reflections have been called forth by a letter from a correspondent in San Antonio, Tex., who complains of the low fees charged by many physicians of that city. He writes: "The average San Antonio physician has the reputation of being a fifty-cent doctor, and really there are men here who will make a visit for that amount, and, if they fail to realize that vast sum, will not hesitate to make a reduction. I have been informed that there are medical gentlemen here who will take an obstetrical case for five dollars cash, but if they have to wait for the money a fee of ten dollars is charged. This sounds ridiculous, but it is only too true. However, there is another class who have endeavored to raise medical fees somewhat; they charge fifty cents for office prescriptions, one dollar a visit, and fifteen dollars for obstetrical cases. . . . Still, to be just, we have a few men here who have put forth every effort to keep up the dignity of the profession—men who have labored for years to bind up the gaping wounds which avarice and quackery have made in our professional ranks—only to see every effort at reform fail."

We are sorry for our correspondent and for all the honorable physicians of San Antonio who have to contend against underbidders. But perhaps it would surprise them to learn that there are numbers of practitioners, excellent physicians and honorable gentlemen, right here in New York, who see patients at the office for fifty cents, and seldom receive more than one dollar for an ordinary visit at the patient's house, while they willingly attend obstetrical cases for ten dollars, and are sometimes glad to compromise for five dollars cash. Yet such is the case, and no one gets angry over it. Medicine is indeed a noble profession, yet it is also a means of livelihood—a business, in other words—and the great laws of supply and demand are just as inexorable in their workings here as they are in the other divisions of mental or physical activity by means of which we poor mortals earn our daily bread.

Our correspondent says that the West Texas Medical Association has as complete a fee bill as any society, but that it is totally ignored by the "fifty-cent doctors." Of course it is. The West Texas Medical Association might just as well attempt to regulate the price which its members should pay for their hats or shoes. There are all sorts of men in medicine, as there are in every calling—good, bad, and indifferent. And patients who have the means wherewith to pay for the services of a physician in whom they have confidence will not employ a poor doctor because he values his services fifty or seventy-five per cent. less. And, on the other hand, many an excellent physician is obliged to content himself with one dollar, or even fifty cents, for a visit, for the reason that those among whom he practises cannot afford to pay more.

Ours is a noble profession, brother, but, as regards the payment for services rendered, it is ruled by universal economic laws, and those laws we cannot evade.

HYPNONE AS AN ADJUVANT TO CHLOROFORM.

ALTHOUGH over forty years have elapsed since Horace Wells took nitrous oxide gas and, while under its influence, had a tooth extracted without experiencing any pain, we have yet to discover the perfect anæsthetic. Of the many agents which have been proposed and used for the production of general anæsthesia, none is without its inconveniences and its dangers, and, despite its disadvantages, ether still maintains its ground as, on the whole, the best anæsthetic which we possess. We do not, of course, forget cocaine, but although this has been used with marvellous results in certain operations in which a comparatively small extent of tissue is invaded by the knife, it is hardly probable that it can ever be made available for the more extensive capital operations. And even should it, there would yet remain cases in which the production of general anæsthesia and unconsciousness would be necessary.

The danger of chloroform has been shown to be in direct proportion to the degree of concentration in which its vapor is inhaled, and efforts have accordingly been made, especially by M. Paul Bert, to so dilute the gas that its inhalation may be absolutely without danger. But it has been found that this dilution cannot be continued indefinitely, for a point is at last reached beyond which anæsthesia cannot be produced. And this limit is still within the danger-line.

But it has been known for a long time that the action of the anæsthetics is rendered more prompt by the previous administration of an hypnotic, such as morphine or chloral, and advantage has been taken of this to push along a little further the limit of maximum dilution. M. Dubois recently stated, at a meeting of the Biological Society of Paris, that he had found the new agent, hypnone, of great service in increasing the anæsthetic effect of chloroform. When one centigramme of this drug was given to a dog by hypodermic injection, it was necessary to cause the animal to breathe only a four per cent. mixture of chloroform and air in order to anæsthetize him. A mixture of this strength, as has been shown by Paul Bert, under ordinary conditions produces no effect at all. And, furthermore, in the experiments made by M. Dubois, it was found that the animal would awake from his anæsthetic slumber in about an hour, even though he continued to breathe the diluted chloroform, thus showing conclusively the influence of the hypnone. The same result was obtained by giving two centigrammes by the stomach instead of hypodermatically. No trials have yet been made upon the human subject, but we can see no reason why the drug should not act the same upon man as upon the dog.

Further trials with hypnone may show that it is not a safe hypnotic, and it has already been found that it is not a perfectly reliable one, since upon some individuals it seems to exert very slight effect. But all drugs are more or less uncertain in their action, according to the idiosyncrasies of the individual, and if hypnone acts only in the majority of cases, and acts safely, it will be not without value as an agent to lessen the dangers of chloroform administration.

SUCCESSFUL ANTHRAX INOCULATIONS.

The disbelievers in Pasteur's method for the prevention of rabies, and especially his personal enemies, are wont to adduce in support of their arguments the failure of his inoculation method for the prevention of malignant pustule in sheep. The one class advances it as presumptive evidence that, having been mistaken in one case, he is in error also in the other; while his enemies assert that it is proof conclusive of his charlatanism. Some recent trials of charbon inoculation in Southern Russia would seem, however, to argue in favor of the value of this discovery. (*Allgemeine Medicinische Central-Zeitung.*) During the summer of 1885, Professor Zenkovski inoculated over thirteen hundred sheep on the estate of Bielaserka, in Kherson. As a result of the inoculations with vaccine matter of two degrees of strength, there was a mortality of from 1.8 to two per cent. A third inoculation with anthrax blood was without effect. In November a committee was appointed to test the protective efficacy of these experiments. They selected at random thirty sheep from the herd and inoculated them with anthrax blood, doing the same also to ten other sheep which had not been submitted to the protective experiments. Of the ten unprotected sheep nine died from anthrax, only one escaping. The thirty previously inoculated animals suffered for a few days a slight elevation of temperature, but none died. One was killed by dogs, and another died two weeks later from pleuropneumonia, but in neither of these were anthrax bacilli found either in the blood or in the tissues.

This would seem to be a fairly conclusive test of the protective value of inoculation, in anthrax at least. And as the annual loss among sheep from malignant pustule, in the Government of Kherson, is from twelve to twenty per cent., the reduction of the mortality to two per cent. is naturally regarded by the proprietors as a great gain.

INTUBATION OF THE GLOTTIS.

We have alluded on several occasions to the practice of intubation of the glottis as a substitute for tracheotomy in membranous croup. The operation was first successfully devised and carried out by Dr. Joseph O'Dwyer, of this city, and in his hands has been attended with some degree of success. Recently the instruments have been procured and used by Dr. T. E. Waxham, of Chicago, and by Dr. E. Fletcher Ingals, of the same city. The former, at last accounts, had tried them in eleven cases, with four recoveries. In the *Journal of the American Medical Association*, for February 6th, Dr. Ingals states that he has employed intubation in two cases, and although both patients died, he is favorably impressed with the possibilites of the tubes.

The operation can be done so easily, it is so free from danger, it so promptly relieves serious symptoms, that Dr. Ingals believes it will become established as a standard therapeutic procedure among general practitioners.

He says: "Looking at the intubation of the glottis from our present standpoint, it seems well adapted for the following cases:

"1. For diphtheritic and croupous stenosis of the larynx occurring in children under three and one-half years of age.

"2. For cases of the same affections in older children in which from any cause the physician wishes to defer the operation of tracheotomy.

"3. For those cases in which consent to tracheotomy cannot be obtained.

"4. For those cases in which proper nursing could not be secured.

"5. For severe cases of spasmodic croup in children less than ten years of age.

"6. For simple stenosis of the larynx, not diphtheritic, in children.

"7. With proper-sized tubes it might be of value in the treatment of various forms of laryngeal stenosis in adults."

The Association of American Medical Editors.—The next meeting of this body will be held the Monday evening preceding the opening of the next session of the American Medical Association in St. Louis, Mo. In view of promoting its success *The American Lancet* makes the following suggestions, viz.: "That instead of the usual gathering, for a few speeches, it be made more of a social affair. To make editors better acquainted with one another in a personal way is certainly desirable. To advance such acquaintance there is nothing so effective as a dinner. Hence it is suggested that the officers arrange for this in a proper way."

News of the Week.

Statues to the French Physicians.—The French, above any nation, appear anxious to honor the memory of distinguished medical men by erecting statues of them. Efforts are now making to raise money for statues to Bretonneau, Velpeau, Trousseau, and Bouley.

The Congress of German Surgeons holds its fifteenth annual meeting in Berlin, April 7th to 10th.

Oleo-resin of Kava Kava as a Local Anæsthetic.—Dr. L. Lewin, author of "Untoward Effects of Drugs," has been making some experiments with kavakava, during the course of which he has discovered a substance, residing in the oleo-resin, which he declares has similar properties, as a local anæsthetic to cocaine. At the suggestion of Dr. Lewin, Messrs. Parke, Davis & Co., have prepared an oleo-resin of the drug, and from experiments made with it at their laboratory, the reports of its peculiar anæsthetic action are likely to be corroborated by the profession.—*Medical Age.*

International Medical Congress.—We have received an article on the International Congress in which such gentlemen in the United States and the Canadas as withdrew from the Congress are characterized as "wide-mouthed soreheads," "monkeys," "parrots," "wild asses," "kangaroos," and "skunks." The author asserts that all "this noise and din about the Congress is but the expression of disappointed ambition on the part of a few conceited orang-outangs." At a recent meeting of the Philadelphia County Medical Society there were one hundred and sixty-nine members who voted against the Congress, as at present organized, to thirty-nine members who voted for it. "Orang-outangs" must abound in Pennsylvania. The communication is anonymous, and it is well for its writer that it is so.—*American Practitioner and News.*

The "Jaw-jerk" is the euphonious and alliterative term recently contributed by neurology to medical science. It is different from, but in a manner, correlative with, the "chin-reflex." The latter is a superficial or skin reflex, the former a deep reflex, analogous to the ankle-clonus, and obtained by suddenly depressing the lower jaw and putting the masseters on the stretch.

Dispensing Poisons.—A bill has been introduced in the New York State Legislature providing that after the first of next January it shall be unlawful to sell any sulphate or preparation of morphine or opium (except paregoric and preparations containing two grains or less of opium to the ounce) except from bottles or packages with scarlet labels.

The Pennsylvania League for the Protection of Scientific Research is the title of an association recently organized in Philadelphia, and having for its object the prevention of any new legislation regarding vivisection. Dr. H. C. Wood is President.

The German Government and Secret Remedies.—The Berlin Committee for the "Suppression of the Nuisance of Secret Remedies" have decided to present a memorial to Prince Bismarck with the following propositions: 1. In place of the imperial ordinance of January 4, 1875, there ought to be issued one which assigns the preparation, and the keeping and offering for sale, of all kinds of medicaments, inclusive of secret remedies and pharmaceutic specialties for sanitary purposes, in retail, exclusively to the apothecaries' shops. 2. For the restriction of the sale of secret remedies in the apothecaries' shops there ought to be instituted an imperial board, acting as a technical central office, having the function to examine and test every secret remedy before permitting it to be sold; to fix the price of such remedy; and to determine whether the drug or compound may be issued to the public otherwise than in the form of a physician's prescription. 3. To prevent an inundation of the market with foreign secret remedies and pharmaceutical specialties it is suggested that they should be subjected to a duty *ad valorem.*

Meat Lozenges and Meat Suppositories are the latest contributions to elegant pharmacy. It may be truly said that the druggist's art has made both ends meat!

A Neurological Society in London.—A neurological society has been organized in London, with Dr. Hughlings Jackson as President, and Drs. S. Wilks and Sir J. Crichton Browne as Vice-Presidents. The scope of the society includes physiology and psychology.

Medical Legislation Opposed by Homœopaths.—The daily papers state that at the monthly meeting of the New York County Homœopathic Medical Society last week, the Committee on Legislation reported against the bills about the appointment of a State Board of Examiners for the purpose of licensing physicians, especially that bill which provides that the board should consist of nine members, six of whom should be members of the regular school of physicians and only three of the schools of homœopathy and eclecticism.

College of Physicians and Surgeons.—We learn that Dr. J. C. Dalton, President of the College of Physicians and Surgeons, has filed with Superintendent D'Oench plans and specifications for the new college building in Tenth Avenue from Fifty-ninth to Sixtieth Streets. It is to cost about $250,000. The structure is to be four stories high and 140 by 182 feet. The front will be of terra-cotta and brick. W. W. Smith is the architect.

The Death of Dr. Amédée Dechambre, of Paris, is announced. He was editor of the *Gazette Hebdomadaire*, and was the *doyen* of the Parisian medical press.

Popular Prejudice against Physiology.—There is a curious popular prejudice against the teaching of physiology in the common schools. This has been illustrated by the story of the old lady who withdrew her daughter from a boarding-school because she "didn't want her to be taught about her insides." Reports state now that physiology is not a popular science in the rural districts of Pennsylvania. It is stated that in some parts of the State the school authorities find great difficulty in enforcing the law passed at the last session of the Legislature compelling the study of physiology and hygiene with reference to the effects of alcohol on the human system. Parents have objected in some sections to their children pursuing the study, and children have refused in others

under their parents' instruction. At Frankstown the school directors have encountered the latter difficulty, and a strong resolution has been adopted by the board with a view to meeting it, which they say they are determined to enforce.

Medical Practice Bill.—A bill to establish a medical board of examiners and licenses, and to regulate the practice of medicine and surgery in the State of Ohio, and to define the duties and powers of such board, will, says the *Cleveland Medical Gazette*, be presented to the Legislature of Ohio. Its provisions are much like those of the Minnesota law.

Dr. W. E. Johnston.—A cable despatch from Paris reports the death, February 14th, of Dr. W. E. Johnston, formerly of Sidney, O. Dr. Johnston was sixty-three years of age, had resided in Paris and practised medicine there since 1851, and had visited his native land only three times since first going to Paris. Dr. Johnston had been in feeble health for some time. He was one of the leading American physicians in Paris, and was well known to many of his countrymen and medical colleagues who visited that city. One of his latest letters to this country was directed to The Medical Record, and was upon the subject of the troubles of the International Medical Congress. Dr. Johnston was for many years a correspondent of the New York *Times* over the signature "Malakoff."

Died in the Discharge of Duty.—Another victim to the dangers of his professional work is reported in the person of Dr. James A. McCaughin, one of the volunteer staff at the Albany Penitentiary during the typhus epidemic. He was stricken with the disease about two weeks ago, and died on February 13th. Dr. McCaughin was about twenty-five years of age. He is the second doctor who has fallen there in the discharge of his duties. There are only three cases of typhus among the prisoners now.

The Latest "Habit."—People appear to be able to acquire any morbid habit, from eating pie t.i.d. to taking opium. The *Medical Herald* reports the case of a man who contracted the habit of taking gelseminum. This he followed until he was able to take a fluid ounce at a single dose. He finally sank into hopeless idiocy and died in a stupor. One curious physiological effect was that his hearing became singularly acute. Perhaps otologists can make use of the fact.

Another Malarial Germ.—In Friedländer's *Fortschritte der Medicin* is contained an original article by Prof. Marchiafava and Dr. Celli, of Rome, describing the results of their studies on the nature of malaria. Their work was conducted for six weeks in the most dreaded section of the Roman Campagna. As a result, something truly wonderful has been found, namely, a micro-organism that is situated within the red blood-corpuscles and there leads a parasitical life. This relation to the red blood corpuscles is an absolute novelty, the micro-organisms that have been so far described in the blood being suspended in the plasma. The researches of the gentlemen named dispose of the bacillus of malaria described by Klebs and Tommasi-Crudeli.—*Weekly Medical Review.*

Reviews and Notices.

Practical Human Anatomy. A Working Guide for Students of Medicine, and a Ready Reference for Surgeons and Physicians. By Faneuil D. Weisse, M.D., Prosector (1863–65) to the late Valentine Mott, M.D., LL.D.; Emeritus Professor of Surgery and Surgical Anatomy, Medical Department of the University of the City of New York; Professor of Practical and Surgical Anatomy, Medical Department of the University of the City of New York; Professor of Anatomy, New York College of Dentistry. Royal octavo, 468 pages of text. Illustrated by 222 lettered plates. New York: William Wood & Co. 1886.

An original work in anatomy is a conception quite difficult to realize. Dealing as it does with solid, incontrovertible facts, anatomy is a study which is generally narrowed to their systematic arrangement and detailed statement. Any departures from the ordinary routine must be made in one or both of these directions. From such a standpoint, Professor Weisse has given us a work somewhat original in design and thoroughly practical in its application of principles. Twenty years of teaching in practical anatomy have eminently fitted him for the task. Nature has been his text-book, and he has studied and reviewed its different pages with the single conscientious purpose of causing others to see with his eyes and interpret with him her many mysteries. It is clinical anatomy, so to speak, with the body on the table. His method of examining the body, and in detailing its appearances, is that of the skilled instructor who knows the wants of his students. They look over his shoulder while he makes his dissections, and the different stages of the study are fixed by the wonderfully realistic lithographic plates, prepared from elaborate sketches on the spot by the talented artist, Mr. Maximilian Cohn. So far as the dissections go, they make the study of anatomy as instructive and profitable as is possible without the actual presence of the body.

As before intimated, the plan of the work is in a great measure original. It is the outgrowth of a careful and loving study of the human body, extending over many years of careful preparation—the chart of a pilot who has personally sounded every fathom of his course. It is only possible to summarize an idea of its plan to enable the student to realize its scope and appreciate its excellences. Its basis is the division of the body into practical dissections, with their successive description and illustration. In other words, the different regions of the body are dissected and described in a natural order and practical manner, so that any student can appreciate the number and relation of the different organs in their respective planes. The illustrations include 153 full-page plates, comprising 51 plates of 132 original figures, 6 full-page plates from standard authors, 9 plates of 25 figures from other works, and 15 original text-figures. The descriptions of the dissections are systematic, terse, and thoroughly in keeping with the classical anatomical nomenclature of the day. They are indeed models of their sort, and leave nothing to be desired for the student who wishes to understand the subject in all its practical bearings. While saying thus much for the text of the work, we have much more of praise for the plates. They are indeed wonderful in their way, as faithful studies of actual conditions, and represent an amount of work on the part of author and artist which cannot fail to be appreciated by the student and practitioner. Especially will this be the case when it is known that the author has generously presented these plates to the volume, so that the price of the latter is no more than that for an ordinary text-book of its size. Typographically the volume is a model of its kind, William Wood & Co. having shared with the author the laudable ambition of making it the leading one in its department.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MATERIA MEDICA AND THERAPEUTICS.

Stated Meeting, Wednesday, January 27, 1886.

JOHN C. PETERS, M.D., CHAIRMAN.

DR. ANDREW H. SMITH read a paper on

THE TREATMENT OF DROPSY WITH APOCYNUM CANNABINUM.

Apocynum Cannabinum (to use the preparation given by Dunglison), as employed in medicine, consists of the bark of the root of the plant having the above botanical name.

Popularly it is called Indian hemp, which name it shares with the utterly different drug cannabis indica. It is also called "wandering milkweed," and this name also it is compelled to share with another member of the same family, viz., androsæmifolium. This latter is often substituted for the apocynum cannabinum; and as it possesses active emetic and cathartic properties has probably contributed to discredit the diuretic virtues attributed to the latter by producing undesired and, indeed, untoward effects.

Apocynum cannabinum is an indigenous plant, and has long been known to the American profession. Its value in removing serous effusion from the pleural and peritoneal cavities so impressed Dr. Rush that he called it the "vegetable trocar." It was employed by the late Dr. Mott, but he considered it too active for any but sthenic cases. The attention which it has received in more modern times, scanty as it is, is due chiefly to the writings of Dr. Hervey Jewett, of Canandaigua, N. Y.

In a paper read before the New York State Medical Society, in 1869, and published in the "Transactions" for that year, he speaks in the most enthusiastic terms of his success in curing dropsy with this drug. He says: "As a tonic and diuretic I regard it as more efficient in the cure of general anasarca and in removing the accumulation from serous sacs than all other remedies known to the profession."

He recommends that in atonic dropsy, the patient being depressed and exhausted, small doses be given at short intervals. In sthenic cases, however, large doses should be employed, combined with potassium acetate or spirits of nitre. He adds: "If not complicated with organic kidney disease, there is invariably a rapid cure;" and "when incurable cardiac and other complications exist, and the effusion is the result of debility, it is the only remedy in my hands that has not disappointed me in giving temporary relief, promoting comfort, and prolonging the life of the patient."

Out of a large number of cases in which he had used this medicine successfully, Dr. Jewett cites three—one of cardiac dropsy, one apparently ovarian, and one in which there were hydrothorax, ascites, and general œdema. All were cured in a brief period. The preparation he employed was a decoction made with one drachm of the bark of the fresh root to eight ounces of water. Of this the dose was half an ounce every six hours.

At a meeting of the Medical Society of the County of Kings (N. Y.), in May, 1875, Dr. Hutchins read a paper, in which he referred to the experience of Dr. Jewett, and related a case of his own in which a man, sixty years of age, having general anasarca, complicated with pleuritic effusion and hydropericardium, was suffering from extreme dyspnœa, the result of the enormous distention. After the failure of all the expedients used to excite the kidneys, trials were made with the apocynum, using various specimens and preparations from well-known drug houses. All these were without effect, but when some of the drug was obtained from Dr. Jewett, of his own gathering, in forty-eight hours after the administration was begun, "the man who had been so frightfully distended was reduced to a skeleton."

Dr. Hutchins also relieved two cases of scarlatinal dropsy and one of phlegmasia alba dolens. He also spoke of the case of an old gentleman who was subject to attacks of dyspnœa from effusion into the pericardium, which were speedily relieved by very minute doses of the fluid extract frequently repeated.

For a letter received from Dr. Jewett by Dr. Hutchins, see MEDICAL RECORD, vol. x., p. 460.

In the discussion which followed, DR. ARMOR expressed the belief that the drug would be found useful chiefly in general anasarca, and in non-inflammatory serous dropsy. If the effusion was the result of serous inflammation, the lymph covering the serous surface would be a barrier to absorption. Dr. Armor had used apocynum with varying results, sometimes procuring a marvellously rapid reduction of the dropsy, and in other apparently similar cases obtaining no effect whatever. In these latter cases he had been equally unsuccessful with all other diuretic agents.

My own personal knowledge of the use of this drug is limited to its employment in three cases. The first was one at St. Luke's Hospital, some ten years ago, which I saw by the courtesy of Dr. McLane. This was a case of renal disease, with scanty urine and threatenings of uræmia. All the usual diuretic remedies had failed, when an infusion of apocynum excited profuse diuresis, and the danger was averted. The second was a case of my own, at the Presbyterian Hospital, in which the remedy was tried for the relief of cardiac dropsy. The result was not satisfactory, possibly owing to lack of care in the selection of the drug.

The third was one which occurred at the same hospital in October last. A woman, about forty years of age, had advanced chronic nephritis, with extreme incompetency of the mitral valve. There was general anasarca, including the face, with a large amount of peritoneal effusion, and the lungs were œdematous. There was extreme dyspnœa, the face was cyanotic, and the mind wandering. The daily amount of urine varied between six and twelve ounces. The usual list of diuretics had been exhausted with no benefit, and I remarked to the house staff that it seemed scarcely worth while to annoy the patient with further medication. However, as a last effort, a decoction of apocynum was prescribed, and with most gratifying results. In thirty-six hours the urine had increased to thirty ounces, and the urgent symptoms had subsided. Since then the patient has been fairly comfortable, and she is to-day in a much better condition than that of four months ago.

As to the mode of action of the drug, it would seem that it can scarcely be by direct stimulation of the glandular structure of the kidneys, else we should not find it valuable in scarlatinal dropsy, for instance, in which we suppose the kidney to be already in a state of irritation. Nor can it be through general increase of arterial tension, since apocynum has succeeded when digitalis and convallaria had failed. I would hazard the conjecture that the action is a special one upon the renal plexus, causing increased vascular tension in the kidney itself.

The drug has tonic as well as diuretic properties. Its taste is not disagreeable, though strongly bitter. It appears to me that it would have a favorable effect in atonic gout, with insufficient renal excretion as one of its factors.

In accordance with the rules of the Section the discussion of this important paper was postponed until the next meeting, but suggestions were made by Drs. Fox, Billington, Putnam-Jacobi, Fanning, Amidon, J. C. Peters, and others.

Then the discussion on the "Local and Dietetic Treatment of Chronic Rheumatism" was opened by Dr. Amidon.

At the next meeting a paper will be read by Dr. Billington on "The Treatment of Amenorrhœa with Permanganate of Potash."

Dr. A. H. Smith's paper will be discussed in full, and further discussion will take place on the treatment of chronic rheumatism. Physicians having experience with apocynum in the treatment of dropsy, will please communicate with Dr. A. N. Smith, or the chairman.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, January 8, 1886.

BEVERLEY ROBINSON, M.D., PRESIDENT, IN THE CHAIR.

(Concluded from page 141.)

THE PRESIDENT then reported two cases of

PERNICIOUS ANÆMIA.

CASE I.—Elizabeth K——, aged thirty, admitted to Dr. Robinson's service at St. Luke's Hospital, October 19, 1885. Dr. Mabbott, house-physician; notes furnished by Dr. E. B. Dench, Sr. The patient was a nursemaid. Her family history was negative. Denies venereal disease and the use of alcohol. Five years ago she fell and hurt herself. Since then the menstrual periods have been scanty, sometimes occurring every two weeks, sometimes every three or six weeks, and painful, the pain beginning two days before the flow, and lasting through it. Three years ago she had intermittent fever, tertian type, lasting about six months.

In December, 1884, she was exposed to wet and cold; does not remember whether during menstruation or not. Soon after had a chill; began to have severe pain over the hypogastrium and left inguinal region; vomited and had dyspnœa. For several days the temperature was 105° F., and for two weeks the symptoms, with the fever, continued. Then she got up for two weeks. At the end of that time (early in January) the pain, etc., returned, though the fever was less marked, and there was little vomiting. The urine was scanty, dark colored, burned when passed, sometimes had to be drawn, and once, for twenty-four hours, there seems to have been suppression. She had considerable pain in the back, much headache; had no œdema or ascites, no delirium; menstruation continued irregular and scanty; had much leucorrhœa. Had pain on pressure over uterus, and in left inguinal region. Thinks there was enlargement in hypogastrium. She remained as above stated until April, 1885, then got up. Two weeks later had a return of the symptoms, with diarrhœa; the stools often contained mucus, but no blood. For some time she was fed by rectum, retaining nothing on the stomach. There was much colicky pain and tenderness.

In July she was better for a week or two, then symptoms returned, disappearing about August 1st, to return about the last of August. She generally had considerable backache and leucorrhœa when up.

Two weeks ago pain and vomiting reappeared, though less severe. Has had no diarrhœa, no hemorrhages, no cough of importance. There is no history of pregnancy, abortion, or miscarriage. Has not menstruated since May, 1885.

On admission well nourished, anæmic, appetite poor, tongue somewhat coated; pulse, 96; respiration, 24; temperature, 98° F., P.M.; urine, 1.027, acid, no albumen, no sugar, contained urates.

October 20th.—Heart: Apex in fifth intercostal space, three and one-half inches from the median line. Distinct systolic murmur, loudest in second intercostal space, one inch from the left border of the sternum, also heard in the first and third spaces. Slight venous hum in the neck. Lungs negative. Moderate sensitiveness in epigastrium, and rigidity of rectus muscles. Slight sensitiveness in right ovarian region. Lower extremities negative. Vaginal examination: In the right cul-de-sac there is an indistinct outline of a soft body very similar in shape to an ovary, quite painful on firm pressure, of soft consistency. Same sensation not felt on left. Cervix quite far back in the pelvic cavity, os small, cervix conical—not enlarged. Uterus not distinctly movable, os points somewhat to left; uterus embedded in a mass extending in front of it and to the right, probably a pelvic cellulitis, probably double ovaritis with descent on right side; some anteflexion.

October 21st.—Began to menstruate.

November 3d.—Vaginal examination by Dr. James B. Hunter: Both ovaries probably constricted by the mass of exudation above the uterus, whence the pain and vomiting; mass felt behind the uterus is an ovary, not particularly tender, probably normal; uterus small, not retroverted.

The patient continued to vomit more or less, and complained of pain. The treatment was directed toward relief from these symptoms, and consisted in the adoption of a variety of measures.

On December 11th the attending physician examined the patient and the following note was made: Lungs: Dulness at right base; posterior breathing cannot be heard at right base; probably some effusion. Vaginal examination: Right vaginal cul-de-sac contains smooth, somewhat globular mass of infiltrated tissue, moderately tender. Left cul-de-sac free. Uterus somewhat movable. No mass felt per rectum except fundus uteri. Probably suffering from tubercular peritonitis. Examination of urine: 1.016, alkaline; albumen, small amount (three per cent); no sugar; few pus and epithelial cells, much ammonia urate. Urine drawn at 8 P.M., 1.018, faintly acid, albumen trace, many red blood-cells, few hyaline casts and sodium urates.

December 13th.—During the night was somewhat delirious. This morning pulse is rapid and feeble. Abdomen distended and tympanitic, patient semi-comatose. Patient remained semi-comatose during the day and died at 9.20 P.M.

Autopsy.—Body is emaciated, rigor mortis is faintly marked, no œdema. Bruise on forehead two inches by one and one-half inch in diameter. Diaphragm is at fourth rib at either side. Bowels very greatly distended. Peritoneum is normal. Pleura: Adhesions at left apex but no fluid in either cavity. Heart is small, valves are crepitant, muscular tissue yellowish, cavities moderately dilated. Lungs: Left is normal; right congested and moderately œdematous. Spleen normal. Kidneys are normal in size, organs lobulated, capsules not adherent; a good deal of fat in both organs, in the cortex. Bladder normal except a zone of intense hyperæmia about the orifice of left urethra extending up mucous membrane of the urethra about an inch. Ovaries are both normal, and the Fallopian tubes are normal. Uterus is normal. No evidence of pelvic cellulitis or cœliac peritonitis. Liver: Enormous amount of fat. Stomach: Mucous membrane is anæmic; common bile-duct is pervious. Intestines are enormously distended with gas and fluid fæces. Brain is intensely anæmic.

Microscopic Examination.—Heart: The transverse striæ are not distinct; the muscle-cells are granular, and in places distinctly fatty. The liver is so fatty that it floats in water; the liver cells can hardly be distinguished. Kidneys enormously fatty; fat everywhere within the tubes; there is no increase in the fibrous tissue.

CASE II.—J. B——, aged thirty-five, single, cook, entered St. Luke's Hospital, October 30, 1885. Family history negative. Had small-pox fifteen years ago; intermittent fever two years ago. Menstruation always regular; no uterine disturbance. Has always been strong, but complexion has been pale. For the last three years has had occasional feelings of epigastric oppression and slight pain shortly after eating, relieved by vomiting. Apparently the symptoms have not increased to any extent until the last illness. October 28th, about 6.30 P.M., suddenly felt dizzy; had feeling of great oppression over

epigastrium, but not much pain; severe pain in the back of head, and then had a large hæmatemesis of light fluid blood. Vomited blood, which became darker and clotted, at intervals, for three hours, entire quantity being about two quarts; was much prostrated; had severe occipital pain during the night and could not sleep. Vomited the next morning, and in the evening of October 29th had another small hæmatemesis. On the morning of the 30th she had a very dark-colored movement from the bowels. Never passed clear blood; never vomited blood before; never noticed any swelling of the abdomen, nor severe epigastric nor general abdominal pain. Neither has she emaciated at all. No pulmonary, cardiac, renal, or urinary symptoms. Patient drinks much tea and coffee, and moderate amount of alcohol, chiefly beer.

On admission, pulse, 114; respiration, 30; temperature, 99° F., 6 P.M.; urine, 1.024; faintly alkaline; no albumen; no sugar; pus and epithelium. Put on milk diet.

October 31st.—Examination by house-physician: Patient extremely anæmic, but not emaciated. Heart: Apex in fifth intercostal space, within nipple line; first sound over apex slightly impure; soft pulmonary systolic murmur; venous hum in vessels of neck. Lower border of liver, dulness two and a half inches above the free border of the ribs in right nipple line. Spleen negative. Abdomen everywhere resistant, but no sensitiveness in epigastrium, and no distinct mass made out. Slight fulness in epigastrium upon inspiration. Inguinal and axillary glands negative. Lungs negative. No œdema, minute varicose veins on lower extremities.

October 31st.—Examination by attending physician: Distinct abdominal pulsation one inch to right of median line on either side of umbilicus, and at least two inches below; force more marked on either side than elsewhere, more direct than expansile. Pulsation followed up to junction of right and left lobes of liver, and there is a feeling of hardness all along the line of pulsation over, above, and below umbilicus; with slight pressure of stethoscope a soft, blowing murmur heard, and above and to left of umbilicus distinct pulsation is seen.

November 1st.—Allowed beef-tea and eggs.

November 4th.—At 7.40 A.M. had hæmatemesis of nearly one quart of blood; fluid light-colored. Ergotin, gr. ij., hypodermatically. Internally, tannin, gr. x.; brandy, 3 j.; aquæ, 3 j., every half hour from 8 to 10 A.M. Ice-bag on stomach; cracked ice by mouth; nothing else by mouth. At 9.50 A.M. vomiting again, no blood.

November 6th.—Hæmatemesis of above four ounces.

November 12th.—4 A.M.: Temp., 104.6° F. 7 A.M.: Temp., 105.4° F. 9 A.M.: Temp., 104.4° F.

November 19th.—In the evening vomiting; temp., 10 P.M., 103.4° F.

November 20th.—About 10 A.M. patient went into collapse and died.

Autopsy, November 20th.—Body fairly nourished; rigor mortis absent; surface of body anæmic; no œdema. Peritoneum normal. Diaphragm normal on either side. Pleuræ: No adhesions; no fluid. Heart a trifle large, slight hypertrophy of left ventricular wall; valves competent. Lungs anæmic. Spleen rather small; otherwise apparently normal. Kidneys lobulated, surfaces granular, capsules adherent; cortices are a trifle thin, markings not distinct; organs extremely anæmic; fat and cysts in the cortices; suprarenal capsules normal. Pancreas firm; anæmic. Stomach: Mucous membrane thickened; organ anæmic. Intestines: Mucous membrane anæmic. Uterus and ovaries, anæmic. (The blood in the right cardiac ventricle was extremely thin and watery in appearance, more so, indeed, than I have ever seen. There was no ulceration or vascular opening upon the stomach-wall which could explain source of hemorrhages.) In small intestine was contained feculent matters colored with bile. In large intestine, and in small intestine for some distance above ileo-cæcal valve, was a fluid material very slightly colored with the bile and seemingly the remains of the enemata employed. There was no coating anywhere in the large intestine by undigested enemata, as sometimes occurs with beef-blood enemata. Example seen in St. Luke's Hospital several years ago, in which cæcum was filled with undigested beef blood, which apparently occasioned uncontrollable vomiting and death. Rise of temperature before death was supposed to be, (1) preagonistic, (2) due to sepsis, or (3) uræmic. Urine was examined and found to contain no urea some hours before death. Intravenous injection of saline solution had been thought of, and every preparation made for employing it, but the indications did not seem to be formal, in view of the small amount of blood lost in the latter days of life. Would it have been advisable—or, in such a case should intravenous injection of defibrinated blood (if any injection be made) be decidedly preferred? Blood examined under microscope after death showed no special change in relative number or appearance of red and white blood-corpuscles. Corpuscles were not counted.

Microscopical examination.—The following report has been furnished by Dr. Frank Ferguson:

1. Heart: Muscle-cells are unusually granular; transverse striæ are not plainly seen; some of the cells have undergone fatty degeneration. Organ very anæmic.

2. Liver-cells around the branches of the hepatic vein are pigmented; central veins are dilated; cells of the organ throughout are cloudy and granular. There is considerable fat at the periphery of the acini. Liver is anæmic.

3. The kidneys are very anæmic. Epithelium lining tubules granular very generally, and in places fatty.

4. The red marrow contains an unusual amount of fat.

Dr. Ball remarked that he was present at the post-mortem examination, and that there was no lesion found in the stomach to account for the hemorrhages. Taking into account the fact that the woman had been anæmic, he was inclined to the diagnosis of pernicious anæmia, that is, anæmia independent of any lesion apparent to the naked eye. The woman, when she was admitted to the hospital, had evidently lost blood and presented the appearance usually seen under those circumstances, and among the measures resorted to were rectal injections, which we all knew did not amount to much in the way of affording nourishment.

Dr. E. G. Loring said that in the eye, in cases of pernicious anæmia, large numbers of minute hemorrhages could be seen, and he thought that without very careful examination of the finer blood-vessels one could not say that rupture had not taken place.

Dr. Ball said that unquestionably there was rupture of blood-vessels in the stomach to give rise to that amount of hemorrhage, but to the naked-eye inspection the points at which they had ruptured could not be seen.

The Society then adjourned.

The Function of the Vermiform Appendix.—Dr. John H. Cipperly, of Troy, sends us an abstract of a paper read before the Rensselaer County Medical Society, in which he advances a novel theory concerning the function of the vermiform appendix. The ascending colon is supplied chiefly with longitudinal muscular fibres, while the cæcum has this muscular coat in less than one-half of its length, its lower portion being baggy and flabby. The intestinal contents are expelled through the ileo-cæcal valve into this baggy receptacle, and then are passed upward through the colon with much less rapidity. "Now," Dr. Cipperly says, "in the onward movement of this accumulation, when contraction takes place, the vermiform appendix, by the presence of air and gases in its calibre and secreting mucus, aids in the relief of this passage by averting a certain amount of suction on the walls of the cæcum, and thus modifies or prevents a commencement of intussusception."

Correspondence.

OUR PARIS LETTER.

(From our Special Correspondent.)

A NEW THEORY OF THE ORIGIN OF DIABETES—THE DEATH OF JULES GUÉRIN.

PARIS, February 4, 1886.

AT a recent meeting of the Academy of Sciences, Dr. Boucheron read a paper, in which he enunciated a new theory as to the origin of diabetes and the diet best suited to the affection. Non-hereditary diabetics, said the author, are, like gouty subjects, those who make habitual use of a diet rich in albuminoid substances and in fermented liquors. A certain number of diabetics are also gouty, and they are nearly all azoturics. This observation corresponds with the experimental notion established long ago by Claude Bernard, that a diet exclusively albuminoid equally produces the glycogen of the liver and the glycogen diffused in the organism. Such are, for example, the experiments where dogs nourished exclusively with meat during several months presented hepatic glycogen, and larvæ of flies nourished exclusively with meat free from fat manufacture glycogen at the expense of the albuminoids. Hence it may be inferred that the albuminoid origin of sugar in animals coexists with the carbohydrated origin—the best known. In diabetes mellitus, the sugar derived from the albuminoids is as important, if not more so, than the sugar derived from the carbohydrates. In the therapeutics of diabetes, it is necessary to fix our attention to the sugar resulting from the albuminoids and that produced by the carbohydrates. Thus it would be useful to diminish the ration of albuminoids and that of the carbohydrates at the same time. The diminution of the albuminoids has the effect, not only of reducing the quantity of sugar and that of the collateral carbohydrates, but also of reducing the quantity of nitrogenous effete substances (urea, uric acid, ptomaines). The abstinence from carbohydrates only diminishes the sugar in leaving behind, sometimes to a great extent, azoturia with its dangerous effects; for the danger of diabetes does not exist principally in the sugar, which is but slightly toxic, since there exists a form of diabetes without sugar. The nocive substances of diabetes consist principally of the effete matters of the organism in a state of defective nutrition, which may be formed into two groups—the nitrogenous (urea, uric acid, animal alkaloids), and zoamines according to Boucheron, or ptomaines according to Selmi, or leucomaines according to Gautier. These irritating or toxic effete substances, in circulating in the vessels and impregnating the tissues, produce irritations of the nervous, circulatory, locomotor, digestive systems; lesions of the organs of sense, ocular and auricular diabetides, and lesions of the principal emunctories; lesions of the kidneys, of the skin, of the mucous membranes, of the glands, of the pancreas; finally, it produces toxic terminal effects. Their influence on the nervous system is undeniable. The therapeutical deduction from the above statements is that in limiting the carbohydrated elements, which is sufficient in a certain number of cases, it is well to limit also the albuminoids and alcoholic liquors. Oxygenation and active muscular exercise are necessary to promote combustion; drugs come next—alkalies, arsenic, the bromides, according to the symptomatic indications.

M. Paul Bert, the eminent biologist, has been appointed President-General of Tonquin, much to the surprise of many of his friends; for, whatever may be his merits as a scientist, and taking into consideration his political antecedents, he is regarded as anything but qualified for such an important post—but favoritism goes a great way under the present government of France. Such appointments almost always turn out unfortunate, particularly when, as in the present case, the candidate is a medical man; for, however eminent he may be in his profession, it does not at all follow that he would make a good diplomatist. In fact, the reverse has often been proved to be the case, for many men equally as eminent in the profession as Paul Bert had to relinquish high political posts to resume what they were evidently destined for. It is said that in going out to Tonquin M. Paul Bert will have a wider field for prosecuting his scientific studies than within the walls of the Sorbonne, but I am afraid that if he once gets out there he will have neither the time nor the inclination for such recreation; for, as suggested by your esteemed London correspondent, politics and medicine are quite incompatible unless the medical men who adopt the former will be content to proffer professional advice only. But even in this respect those who have undertaken such a task have, with rare exceptions, proved failures, as it is impossible for any man to do equal justice to two such important sciences as politics and medicine.

Jules Guérin, whose name has been familiar to the profession for more than half a century, died at Hyères, on Monday, January 25th, in the eighty-sixth year of his age. His health had been declining for some time, and he left Paris only a fortnight before his death to seek the rest that he was so much in need of. Dr. Jules Guérin was one of the oldest and most eminent members of the profession in this country. His discussions at the Academy of Medicine, of which he was a most distinguished member, are masterpieces of scientific reasoning, though it cannot be said that he was always in the right. He was a great sceptic, and he marked his place at the Academy as a vigorous disputant, but of the most eccentric character. He stoutly combated the modern theories of cholera and the microbian doctrine of disease. He was altogether sceptical as to the supposed discoveries of Koch and Pasteur, and particularly of the latter in regard to his inoculations for hydrophobia. Notwithstanding the eccentricity of his opinions, he was considered a great authority by his colleagues. He was the author of several important works on deformities of the osseous system, orthopædics, and subcutaneous tenotomy. He was the founder of the *Gazette Médicale* of Paris, and during the last three or four years of his life he was engaged in making out a catalogue of his books, of which he had a vast number, and of those of which he was the author he published, in the form of extracts, a quarterly review, which is a most interesting work, and well worth consulting.

VARIATIONS IN THE DIABETIC DIET.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The sufferer from diabetes who is condemned to use the ordinary gluten loaf must sometimes feel that he is on worse than prison fare. I annex certain recipes which were sent me by a devoted wife, whose husband was suffering from diabetes, and who was also skilled in the culinary art. I suggested to her that she should endeavor to evolve something palatable out of the gluten flour which was to form a principal article of his diet. The gluten is still there, but by turning the prism we practically change and vary the view. I give the directions mainly as they came to me.

Gluten gems.—Mix in a batter two cups of gluten flour, two cups of milk, two eggs, and a sufficient quantity of salt. The mixture must be baked in a *sharp* oven for fifteen or twenty minutes. The gem-pans must be hot and well greased when the gems are put in.

This same mixture may be used for pancakes; also baked in a pudding-dish and eaten for dessert. A sauce of equal parts of milk and water heated together, sweetened with glycerine and flavored with cinnamon, makes it very palatable. The addition of a little sherry wine, *if allowed*, is an improvement. The same mixture baked in jelly-pans and put in layers, with strawberries between each and also on top of the last, is a very fine strawberry

shortcake, or an excellent substitute for it. The *cup* referred to in this mixture represents half a pint. In connection with the matter of measurement, it is worthy of note that sometimes the flour is much heavier than at others and requires much less than two cups.

The almond flour has for some time been placed in the diabetic dietary. The formula beneath was sent me for the preparation of the almond bread.

Take one-quarter of a pound of almond meal and four eggs. Separate the yolks from the whites, and whip the whites moderately into a strong cream. Stir the yolks (well beaten) in lightly, add the almond meal, and bake in a tin in a slow oven. The oven should be as hot as for any other bread, and this quantity will bake in about thirty-five minutes.

Gluten biscuit, when well made, are far more agreeable to the taste than gluten bread. To make these mix together two cups of gluten flour, a scant even teaspoonful of baking powder, a "pinch" of salt, and a sufficient quantity of sweet milk. They are to be baked like other biscuit.

To the sick man diet is of more interest than pathology, and the diabetic patient will presumably derive more comfort from these formulas than from an exact diagnosis of his case, or positive information as to whether his disease be of nervous or glandular origin.

Respectfully,

F. A. Bureall, M.D.

[illegible]

"DR." OR "M.D."?

[illegible]

Sir: I would like to speak of a subject of medical etiquette that has puzzled me somewhat. It is customary for physicians, at least about Boston, to have their cards engraved with the prefix "Dr." to their names. This seems to me wrong, from a medical as well as social standpoint. From a medical standpoint, because the abbreviation "Dr." does not distinguish whether a man be physician, dentist, veterinary, lawyer, or divine, all of whom have the legal sanction, and the first three the sanction of custom, for the use of the term "Doctor." Social customs permit one to place upon his cards, if he so wish, whatever titles he may possess. Now, the term "Doctor" is merely part of a title, and aside from its ambiguity it contravenes the law of etiquette. If written at all before the name it should be thus: "Doctor of Medicine A——." The correct method would seem to be to sign, after the name, such letters as designate the title, as "M.D.," "D.M.D.," "LL.D.," etc.

R. Eugene MacDonald, M.D.

[illegible]

[Our correspondent is undoubtedly right. Physicians' cards should be printed with the title "M.D." after the name. We have heard the excuse given for the present custom that many people do not know what "M.D." means.—Ed.]

SKUNK-BITE AND HYDROPHOBIA.

[illegible]

Sir: Apropos of the present excitement relating to hydrophobia, I would call your attention and that of the profession to a report of an assistant surgeon, U.S.A., stationed at Fort Riley, Kan., in 1872, and published in a medical journal (the only one at that time), name and month forgotten, at Kansas City, Mo., in which he stated that of fifty cases of hydrophobia that he had collected, a part of which came under his own observation, they were traced directly to the bite of the skunk.

Perhaps some member of the profession, with a memory less treacherous than mine, can give the name of the author and the exact date of the publication of the article, or perhaps the journal referred to, can be obtained, if you give a little prominence to the subject. I know that the article impressed me very strongly at the time, as *almost* establishing the fact that this disease is caused by an inherent poison in the saliva of this odoriferous animal. The skunk referred to is the smaller of the two animals that pass indiscriminately under that name, but which on the prairies of this State are divided into skunks and polecats, the latter being more than as large again as the former, but imparting the same effluvia upon provocation; but, as I remember, the doctor referred to did not charge the polecat with this hydrophobic property.

A. G. Chase, M.D.

[illegible]

[The article to which reference is made was written by John G. Janeway, Assistant Surgeon, U.S.A., and will be found in The Medical Record, vol. x. (1875), p. 177.—Ed.]

New Instruments.

AN IMPROVED ORO NASAL RESPIRATOR.

[illegible] W. H. Glendenning, M.D.

After the publication of Koch's discovery of the bacillus tuberculosis, I tried the various apparatus which had been devised for antispectic inhalations, and found all of them more or less impracticable or useless. The best of them proved to be the so-called Blake-Mackenzie respirator, a modification of an instrument devised by Curschman, in 1880, and subsequently improved by Hausmann. But this instrument, notwithstanding its

great utility, being of metal, was heavy and cumbersome, and most patients preferred the neat little celluloid instrument of Meyer and Metzger, of London; but this being unprovided with the rim of soft rubber tubing, permitted the free passage of air between the instrument and the face instead of through the medicated sponge. It struck me that if this little instrument could be provided with the soft rubber tubing of the Blake-Mackenzie, we could have a neat and serviceable respirator; but on applying to the instrument-maker, I was met with the objection that there was no cement by which the soft rubber could be attached to celluloid.

Since then Messrs. Tiemann & Co. have made for me an instrument combining the advantages of the two, which, with the improvements I am about to mention, makes it the most perfect respirator that has as yet been devised, and one which, for antiseptic inhalations, is second only to the costly and often inaccessible pneumatic cabinet. By referring to the above cut, it will be seen

that in form it resembles the Blake-Mackenzie respirator; but, being made of hard rubber, it is lighter and less ungainly in appearance.

A serious objection to all the oro-nasal respirators that I have seen is, that the valves closed imperfectly, and being made of rubber cloth, would soon curl up and become entirely useless. To overcome this difficulty, I have provided the valves over the lateral openings of the instrument with brass springs which close tightly during inspiration, and thus force the air to pass through the medicated sponge contained in the anterior cup of the instrument. As the sponge or the absorbent cotton in this cup offers sufficient resistance to the passage of air during the expiratory act I have dispensed with the central valve as useless.

Should one of these springs break, and the valve become useless, it may be readily replaced by loosening the screw and inserting a new one, and this can be done at a very trifling cost.

The substances I have thus far used with the most advantage have been eucalyptus oil and the following formula, for which, I think, we are indebted to Mackenzie:

℞. Thymol ..... gr. xl.
Æther. acetic ..... ♏ xl.
Æther. sulph ..... ♏ v.
Creasot ..... ♏ xl.
Terebene ..... ad ℥ j.

Ten drops of either of the above should be dropped on the sponge or cotton. To be effective the instrument should be worn for several hours each day, suspending its use or shortening the duration of the inhalation if the patient complains of headache, or if the face becomes flushed.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 7, 1886, to February 13, 1886.

TILTON, HENRY R., Major and Surgeon (Fort Wayne, Mich.). Granted leave of absence for two months, to commence on or about March 1, 1886. S. O. 8, Division of the Atlantic, February 9, 1886.

SHANNON, WILLIAM C., Captain and Assistant Surgeon. Ordered for duty at Fort Warren, Mass., relieving Assistant Surgeon John M. Banister, who will return to his proper station (Fort Adams, R. I.). S. O. 27, Department of the East, February 6, 1886.

EDIE, GUY L., First Lieutenant and Assistant Surgeon. Ordered for field duty in New Mexico, with troop "K" Eighth Cavalry. S. O. 23, Division of the Missouri, February 8, 1886.

Official List of Changes in the Medical Corps of the United States Navy for the week ending February 13, 1886.

CRAWFORD, M. H., Passed Assistant Surgeon. Detached from the Shenandoah on the 8th instant to await orders.

RUSH, C. W., Assistant Surgeon. Detached from the New Hampshire on the 15th instant, and ordered to the U. S. R. S. Franklin.

THE TREATMENT OF SOFT CHANCRE by means of salicylic acid is highly praised by Dr. Falco, of Barcelona. The sore is washed twice daily with a carbolized solution, and then dusted over with finely powdered salicylic acid. In a number of cases treated by this plan, the average time required for a cure was five and one-half days.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 13, 1886:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

THE OPERATION FOR THE ALLEVIATION OF DEAFNESS.—Dr. Jefferson Bettman, of this city, writes: "In a recent issue of THE MEDICAL RECORD, just to hand, an article treating of 'A New Operation for the Alleviation of Persistent Deafness' attracted my notice. It is merely in the interests of scientific accuracy that I disavow the claims of this operation as an 'innovation.' The operation, as described by Dr. Bates, accords completely with that practised and published by Professor Joseph Gruber, of Vienna, in 1873. The articles treating of this subject can be found in the *Allgemeine Wiener Med. Zeitung*, January 7, 14, 21, 1873, under the full title: 'Die mehrfache Durchschneidung des Trommelfells als Heilmittel gegen primäre oder mit Trübung einhergehende Spannung desselben.' The operation of plicotomy (the division of the posterior fold of the membrane) was, however, described a year previous to this by Lucae (Langenbeck's *Archiv*, Bd. xiii.). As the views of the two eminent Viennese aurists, Gruber and Politzer, militate in so many points of minor or greater importance, it is not surprising that the latter should have advocated the same operation (vide *Wiener Med. Wochenschr.*, 1871) in diametrically opposite conditions of the membrane, *i.e.*, flaccidity or relaxation. Since then much has been written on this subject, and those who are interested will find the complete bibliography in Schwartze's most admirable 'Handbook of Aural Surgery.' The improvement in hearing frequently following the operation (myringotomia multipl.) is almost unexceptionally but transitory in nature. This has induced the majority of experienced observers to abandon it of late. As experience has shown that most of these operated cases gradually lapse into their old state, it at the best requires one or two years to determine accurately the curative effect of the operation."

SUCTION OF THE TUBE AFTER TRACHEOTOMY.—Dr. Suñe y Molist uses a flexible catheter, to which is attached a rubber bulb, in order to remove obstructions in the trachea after tracheotomy. The eye of the catheter is cut off smoothly, and the instrument is then introduced through the tube, the bulb being compressed. The latter, by its expansion, draws the mucus and fluid out of the trachea. It is then removed from the extremity of the catheter, emptied, and again attached while compressed. This operation can be repeated a number of times very rapidly. In this way the dangerous expedient, which is sometimes resorted to, of sucking on the tube is rendered unnecessary. The catheter should be carefully disinfected prior to its introduction.

A NEW MODE OF ADMINISTERING THE PHOSPHATES.—Dr. Cano Quintanilla writes in *El Dictamen* that the phosphates, which theoretically ought to give good results, do not always do so, because of their insolubility. He says that this difficulty can be overcome by making use of cows or goats. He gives two ounces a day of

phosphate of lime, mixed in the feed, to a cow, or five drachms to a goat. In a few days the animals' milk becomes much thicker, and is found to contain a large amount of phosphate of lime in a soluble state. This milk may then be given to patients when the phosphates are indicated. The author has employed this method with success in rachitis.

Mental Strain and Menstruation.—Schrader has found amenorrhœa very common among young women studying midwifery—in one class of 114 students, 65, or fifty-seven per cent., being thus affected. In most of these menstruation ceased immediately after they began their studies, and the writer attributed it to the increased mental activity and the modification of the blood-supply occasioned by the greater demand of the cerebral tissues.

The Treatment of Constipation.—A correspondent sends the report of a case of obstinate constipation cured without medication by the formation of a habit of regularity in seeking an evacuation of the bowels. The first attempts were unsuccessful; but by making the effort at the same time every day, the patient finally acquired a regular habit and has never since been troubled with constipation. The writer says that by habituating the stomach to receive food at any certain hour, a habit is finally formed, and hunger comes at that time. In the same way the rectal nerves may be cultivated so that there is an effort at expulsion of the contents of the viscus at a definite hour.

The Prevention of Cholera.—Dr. A. S. Ashmead writes that when he was in Java, in 1874 and 1875, he was in the habit of using, in cases of diarrhœa, as a preventive of cholera, the mycoderma aceti, or mother of vinegar, in alcohol, with camphor-wood shavings. This was suggested by Pasteur's plan of rapid acetous fermentation with beech-wood. As there was no epidemic of cholera in those years, the value of the prophylactic could not be determined. The writer asks whether this remedy has been tried by others, and if so, with what success.

An Instance of Catalepsy caused by an examination of the ear is related by Dr. Medina, of Chili. The patient was somewhat nervous, and the introduction of the aural speculum was followed by a well marked attack of catalepsy, which was, however, of short duration.

Anatomical Lesions in Addison's Disease.—Dr. Jurgens has made a number of examinations of the abdominal nervous system in Addison's disease. In every case the terminal intestinal nervous plexus was intact; in some instances there was marked degeneration of the ganglion-cells of the solar plexus; and in every case, without exception, there was found gray degeneration of the medullary nervous fibres in the two splanchnic nerves. This alteration was sometimes primary when there was simply atrophy of the suprarenal capsules, and sometimes secondary or consecutive to lesions in the capsules or pancreas. In every case which came under Jurgen's observation, in which the lesions of the suprarenal capsules or pancreas were not accompanied by the bronzed discoloration of the skin, the roots of the splanchnic nerves were found intact.—*Revue Bibliographique des Sciences Médicales*, No. 21, 1885.

Quinine in the Treatment of Asthma.—Among the many drugs mentioned by different writers as occasionally of service in asthma quinine sometimes appears. But it is seldom spoken of as possessing any great value, and seems to be admitted to the list merely from the habit that many authors have of recommending quinine whenever all other remedies have failed. In an article in the *Rivista Clinica e Terapeutica*, for January, 1886, Professor C. Federici speaks much more favorably of the drug, and says that for a number of years he has placed his chief reliance upon it in the treatment of this troublesome affection. The paroxysms of idiopathic asthma occur ordinarily during the night, while the remissions take place in the day, and this periodicity, the writer considers, is sufficiently marked to offer an indication for the use of quinine. He usually gives the bisulphate, though occasionally the valerianate, in three doses of six grains each per diem. The first dose is given at dusk, and the two succeeding ones at intervals of one hour. When a patient is very nervous or is troubled with insomnia, even when the asthmatic paroxysms are absent, he adds half a grain of extract of opium or a third of a grain of extract of belladonna. When the paroxysms are overcome the dose of quinine is gradually reduced. If much bronchial catarrh is present the writer gives, in addition, some ipecac or carbonate of ammonia. Professor Federici claims to have obtained excellent results in the treatment of simple asthma by this method.

Pericarditis after Whooping-cough.—Dr. Racchi relates the case of an infant, aged four months, who was attacked with pertussis of very severe type, resisting the action of the various remedies used. Examination of the chest revealed the presence of capillary bronchitis, with emphysema of the anterior and inferior portions of the lung, but there were no signs of a cardiac affection. The child died, and at the autopsy were found the lesions of a well-marked sero-fibrinous pericarditis. In order to determine the relation of this affection to the whooping-cough, the author instituted a number of experiments upon rabbits. Microscopical examination revealed the presence of schizomycetes in the exudation in the larynx, minute bronchi, and pericardium. These were in the shape of round poli-nucleated cells, and of rods, both endowed with power of motion. Some of the exudation was placed within the larynx of each of those animals, one receiving that from the larynx of the dead child, another that from the terminal bronchioles, and the third the pericardial fluid. At the end of two or three days the animals began to cough, and in eight or ten days the cough assumed the convulsive character of pertussis. Then three other rabbits were similarly treated with the laryngeal exudation taken from those previously experimented on, and at the same time a healthy rabbit was placed in the cage of each one of those with pertussis. Each one of both these sets acquired the affection. An accidental occurrence also gave additional proof of the nature of the disease and of its contagiousness. Two children gained admittance to the room in which the rabbits were placed, and played with them for some time. In a few days each of these children began to have the characteristic cough of pertussis. Two of the rabbits died and two were killed; in one there was well-marked pericarditis, in the others the pericardium was intensely hyperæmic. The author was thus led to look upon the pericarditis as a direct result of the whooping-cough, the schizomycetes being carried to the pericardium through the medium of the general circulation, and finding there a soil rendered favorable by the constant slight traumatism caused by the act of coughing.—*Rivista Clinica e Terapeutica*, January, 1886.

The Philosophy of Drinking Largely.—Not very long ago those unhappy folk who go wearily and sadly, because, forsooth, they are waxing fat, were warned to leave off drinking largely and to minimize the quantity of liquid they consumed (*The Lancet*). Never before, perhaps, was there a more mischievous "fad" imposed on a too credulous public than this reduction of the amount of fluid taken. Now the obese are, by the rotary madness of the crazy in physic, counselled to drink deeply. This, at least, is a safe policy, and whether or not it does anything in aid of the removal of fat, it will certainly not produce the evil consequences which have in too many cases been brought about by the abstinence from solvents and diluents. Our concern is not with the "anti-fat" movement; with this we have no sort of sympathy, except in so far as an accumulation of

adipose tissue may chance to be morbid. Meanwhile there are physiological facts in relation to drinking which ought to be recalled by those who know them, and brought to the knowledge of the unskilled in medicine, because they concern the promotion of health. Thus it is essential that there should be constantly passing through the organism a flushing, as it were, of fluid, to hold in solution and wash away the products of disassimilation and waste. Those who do not recognize the fact that three-quarters by weight of the entire organism is normally composed of fluid cannot fully realize the great need which exists for a copious supply. If there be not a sufficient endosmose, the exosmose must be restricted, and effete matters, soluble in themselves, but not dissolved because of the deficiency of fluid available, will be retained. Take, for example, the uric acid; this excrementitious product requires not less than some eight thousand times its bulk of water at the temperature of the blood to hold it in solution; and if it be not dissolved it rapidly crystallizes, with more or less disastrous consequences, as in gout, gravel, and probably many other less well-recognized troubles. We only mention this particular excrement by way of illustration. In all, it may be fairly concluded that not less than three and a half pints should be consumed by any person in the twenty-four hours, and when the body is bulky four or even five pints should be the average. It is, moreover, desirable that the fluid thus taken should be in the main either pure water or water in which the simplest extracts are held in solution. When fluid taken "as drink" is itself heavily charged with solid matter, it cannot fairly be expected to so entirely rid itself of this burden in the process of digestion and absorption as to be available for solvent purposes generally, although the separation between solid and fluid ingredients of the food is doubtless fairly complete in the processes preparatory to assimilation. The aim should, nevertheless, be to supply the organic needs in this particular abundantly, and with such fluids as are not overloaded with solids, but simple and readily available as solvents. Another urgent reason for drinking freely of bland fluids is to be found in the need of diluents. This is something slightly different from mere solution. Many of the solids of the tissue waste are of a nature to irritate and even disorganize the kidney, if they be brought to that organ for excretion in too concentrated form. There is no reason to suppose that the kidneys are liable to suffer from overwork if the specific excreting power of the kidney-cells be not too heavily taxed. If only the products of disassimilation be diluted, so that they can be passed through the kidney by the simple process of exosmosis, the organ will discharge its function without injury or exhaustion. As a matter of fact and experience, those who drink innocuous and unstimulating fluids freely do not suffer from kidney trouble, but are almost uniformly healthy, at least so far as the excreting functions are concerned. It is a popular fallacy that the kidneys may and ought to be relieved by the determination of fluid to the surface of the body and perspiration. Except in cases of organic disease of the kidney, or where, as in the elimination of a special product, it is desirable to use the skin as an emunctory, the fluid diverted from the kidney is wasted so far as flushing purposes are concerned.

Registration of Veterinary Surgeons.—At a meeting of the New York State Veterinary Society, held in the Cooper Union last week, it was decided to send a committee to the Legislature to urge the passage of a bill compelling veterinary physicians and surgeons to register in the County Clerk's office. Persons not so registered are to be prohibited from practising veterinary medicine or surgery for compensation or reward. No person is to be entitled to register unless graduated from a legally chartered college or university, organized at least one year before the passage of the bill. Any person who has been in veterinary practice for a livelihood at least five years preceding the passage of the proposed bill, without having obtained a diploma from a college, may register upon depositing with the County Clerk affidavits concerning his term of practice. The book in the County Clerk's office is to be known as the "Veterinary Medical Register," and every man whose name goes on it must pay a fee of $2. Fraudulent registration or violation of the act is to be made punishable by fine or imprisonment, or both.

Inversion of the Uterus.—At a meeting of the Surgical Society of Paris, held on December 23, 1885, M. Defontaine reported the case of a woman who had suffered from inversion of the uterus for thirteen years. She had been confined at this time, and apparently everything had progressed favorably, but she soon began to suffer from metrorrhagia. A tumor was discovered, and diagnosed as uterine polypus, but upon an attempt being made to remove it with the écraseur it was found to be the inverted uterus, and the surgeon desisted from further efforts to remove it. M. Defontaine saw the patient one year ago, and after numerous attempts to reduce it by lateral taxis and Gariel's pessary, he determined to operate. He employed an elastic ligature, and at the end of twelve days the tumor became detached. The woman is now in good health.

Treating Dysentery with Cocaine.—We have received many letters inquiring about Dr. Winter's method of treating dysentery with cocaine. His treatment of a young child was as follows: Ten drops of an eight per cent. solution, in one drachm of water, were injected into the rectum, which relieved the tenesmus for two hours; then twenty drops of the same solution, in a drachm of water, were injected. This was repeated every five, six, or eight hours, according to indications.

Illegitimacy in Peru.—Dr. J. W. Kales, of Franklinville, N. Y., writes that the distinction which Lima enjoys, in respect to its number of illegitimate births, is apparently not of recent growth. He quotes the following extract from a work on geography published in Glasgow, in 1805: "In the province of Quito the Indians are said to have a custom of a very singular nature. A young man, instead of wishing to be the first to gain the affections of her whom he wishes to espouse, is seldom willing to accept her hand until she has been not only courted but enjoyed by another, alleging that it degrades him to marry a woman of whom no other man has endeavored to make a conquest. . . After marriage the women are remarkably chaste."

Providing for the Insane in Tennessee.—During the past two years Tennessee has been actively improving the accommodations for her insane. The hospital at Nashville, under the care of the distinguished alienist Dr. John H. Callender, has been overcrowded for several years. A new Asylum at Lyon's View, near Knoxville, in East Tennessee, is nearly completed, and was expected to be open for patients in December last. The State has also made an appropriation for another asylum in West Tennessee, and a commission is now engaged in selecting the most appropriate location.—*Journal of the American Medical Association.*

Deodorized Iodoform.—A correspondent asks us for something that will deodorize iodoform in powder. Herr Oppler recommends the following formulæ: Iodoform (pure), 50 grammes; roasted coffee, in very fine powder, 25 grammes; a few drops of spirits of ether; or, iodoform (pure), 2 grammes; paraffin, 10 grammes; roasted coffee, in fine powder, 0.3 gramme.

Delegates to the American Medical Association.—According to *Public Opinion*, published at Chambersburg, Pa., the County Society, which recently met and elected delegates to the next meeting of the American Medical Association, chose men who are opposed to the policy developed by the present and past managers of the International Congress.

MIRROR-WRITING AND OTHER PATHOLOGICAL CHIROGRAPHY OF NERVOUS ORIGIN.

[illegible] Handwriting, since it bears the stamp of personality more than handwriting, not even excepting speech, since that is evanescent. The written page exhibits the thought petrified. A sound, a word falls on the ear and is forgotten, or only recalled with endeavor; a thousand years may pass and the hieroglyphics of dead Pharaohs present their thoughts living and palpable to the children of to-day. The motto written by the Pompeian baker in the yielding dough of his bread remains unchanged to this very hour, eighteen centuries after its maker has crumbled to dust, overwhelmed by that terrible storm of Vesuvian ashes. It is through his writings that the philosopher or poet, scientist or savant, though dead, lives.

As the members of the body are the servants of the brain to carry out its will in motion, as the vocal organs express its thoughts in sound, so in the act of writing the hand embodies the subtleties of cerebral action. It is therefore in writing that we may find expressed deviations from normal nervous conditions, sometimes too slight to be indicated in any other way.

Before passing to a consideration of the pathology of handwriting, we will first glance at the physiology.

PHYSIOLOGY OF HANDWRITING.—Erlenmeyer, Bianchi and Poore[4] have analyzed the groups of muscles used in the act of handwriting. Says Poore, in the grasping of the pen, in the up and down motions of the fingers, in forming the letters and the swaying motion of the forearm in guiding the pen across the page there is scarcely a muscle from the shoulder to the fingers which is not brought in play.

1. *Act of prehension.*—The grasping of the pen is accomplished by the intrinsic muscles of the hand, the interossei, especially of the first two fingers, the abductor pollicis, the opponens pollicis, and the flexor brevis pollicis. The phalangeal angle of the thumb is maintained by the extensor primi internodii pollicis.

2. *Poising of the hand* is accomplished by the supinators, including the longus and brevis, and possibly the extensors of the thumb.

3. *Stroke movements* are accomplished by the long flexors of the thumb, the flexor profundus digitorum, the extensor communis digitorum.

4. *Movements from left to right* are accomplished by the extensors and triceps; right to left, by the pectoralis.

At no time in the act of writing are less than two nerves called upon to supply the impulse, often more. Marcé[5] was the first to suggest that there is in the cortex an independent centre for writing as well as for speech, with which it is intimately connected. Charcot,[6] Pitres, Lichtheim[7] evolved this idea of a writing-centre into a word-motor representation centre, situated at the base of the left third frontal convolution, near Broca's centre of speech. There are, moreover, the auditory centres, supposed to be situated in the temporal convolution, and the ocular centres, situated in the parietal; but the exact location of these centres and their inter-commisural tracts are problems yet to be solved, and which doubtless will be, as so much interest is felt in it and investigation is directed toward it.

[5] Mémoire sur quelques Observations de Physiologie Pathologique tendant à Démontrer l'Existence d'un Principe coördinate de l'Ecriture et les rapports [illegible]

[6] Rev. de Méd., 1883.

[illegible]

From the hieroglyphic writing of the ancients, from the sculptured signs of Indians and Mexicans, from numerous word signs, as of the Thibetans and Japanese, as numberless as the ideas and as the objects which they represent, our own modern handwriting has attained its peculiar form. Every people, says Bianchi, use the right hand, whether the characters traced are written from right to left, from left to right, or from above downward, or whether the letters flow in succession after each other or are written one by one. The cause of the use of the right hand, and that the formation of the writing should be obtained by a centrifugal movement, are matters which have also been discussed, more especially by Erlenmeyer and Bianchi, as well as others who have written on mirror-writing. Erlenmeyer maintains that the centrifugal motion, whether with one hand or the other, is that which is easiest and most natural. Gestures are so made. The pushing motion is stronger than the centripetal motion. The centrifugal motion is made with the right hand preferably because most motions are performed more readily with the right than the left hand. The cause of this, again, he thinks, resides in the fact that we are left-brained, the left brain is so much better nourished than the right.

However it has come about, we have a handwriting arranged to be written from left to right, with the right hand, either from careful education in the matter or from a deeper physiological underlying cause; a beautiful system, according to some writers, a flowering of our civilization, an elegant outgrowth from barbaric hieroglyphics.

Is this so? On the contrary—does not this writing strain the weakest muscles of the hands, and take four or five times as long as is necessary for the representation of a word? as is shown by the fact that when we wish to have what is spoken written as fast as it comes from the lips, we employ a stenographer. Why are we not all stenographers? Simply because we follow blindly the example set by our ancestors. If we vary, it is only according to some fashionable vagaries in rounding or pointing our letters, and following certain national characteristics. If one-half the pains were taken to teach a child phonography as is to hold the pen in a cramped, awkward position, such as is figured in books for improved penmanship, there would result not only a saving of time, which is something in these days of hurry and struggle for accomplishment of all that is to be done, but a great strain on the muscular and nervous apparatus employed in elaborating writing. In view of the increase of writer's cramp, due to the extraordinary amount of writing to be done by book-keepers, book-writers, teachers, and savants, a new method of writing should be intelligently discussed. That writing is one of the least cast-iron inventions of man is proven by the fact that within the last half century two entirely different methods of representing ideas by written symbols have been invented. These are the phonographic characters and the system of dots and dashes which are used in telegraphy.

It is not only that our present system of writing is too elaborate, our method of holding the pen to form the letters excessively taxing on the small and weaker muscles of the hand, but that the letters, because following each other as they do, necessitate a constant pendulum movement of the forearm from right to left. To write across the page, rather than from above downward, has been said to have originated first because it was easier to move the eyes in a horizontal rather than a vertical plane. Axenfeld [1] quotes the case of a young man who had read excessively, whose head would turn involuntarily to the right whenever he made the attempt to read, an instance which shows that reading from left to right is not wholly without its drawbacks. Is it not therefore greatly to be desired that a writing be devised in which the letters can be formed, as in phonography, unconnected, not requiring such precise and complicated motions to make them legible, and so formed that they can be written from above downward, or in any other direction, and with the left hand as well as the right.

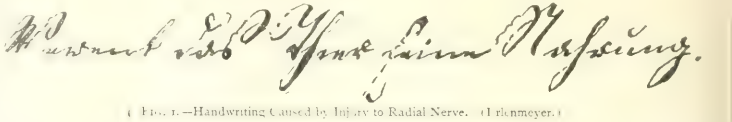

FIG. 1.—Handwriting Caused by Injury to Radial Nerve. (Erlenmeyer.)

Type-writers are an assistance. There is a gain in speed and relaxation of effort to make the letters clearly. They have not been in use as yet long enough to develop the objections which may exist against their use. I can see no reason why there should not be a type-writers' cramp after a while, as there occurs occasionally a telegraphers' and piano-players' cramp.

Many teachers in city schools now make their pupils practise writing with the left hand, as well as the right. Notwithstanding the apparent physiological basis for a right-handedness, I am convinced that in the matter of writing or any other skilled movement, it is more a matter of education than is generally believed. Many surgeons teach themselves, with little trouble, to be ambidextrous.

PATHOLOGY OF HANDWRITING.—Bianchi in Italy and Erlenmeyer in Germany are almost the only ones who have entered into the study of the pathological signification of the handwriting. The subject has been considered in a disconnected way as a symptom of some diseases treated of in various text-books. However remotely alluded to, there has been a general acknowledgment of the value as a diagnostic sign of the handwriting of disease, and an expression of regret that so little attention has hitherto been paid to it.

The handwriting may become pathological through the alteration of any portion of the mechanism involved in its production. This paper includes only a discussion of the changes produced by abnormal conditions of the nervous apparatus.

Alterations in handwriting may be mechanical or psychical, they may be ataxic or tremulous, or a mingling of the two forms. The ataxic is physiological when seen in childhood, before the power of coördination of muscles for the complex act has been acquired. The tremulous is physiological in the handwriting of the aged, in which also is seen a tendency to retrograde into the childish handwriting.

The principal pathological handwritings are:

1. Handwriting resulting from trauma to the nerves.
2. Mirror-writing and agraphia, caused by injury to the cerebral centres.
3. Handwriting of general paralysis, caused by alteration of cerebral tissue.
4. Handwriting caused by sclerosis, cerebral and spinal.
5. Handwriting caused by functional disturbance, including paralysis agitans and writers' cramp.

Traité de Névroses, p. 440. Paris, 1883.

1. *Handwriting caused by trauma to the nerves.*—Samples of handwriting can be shown occasioned by the interference with the conducting nerve-fibres. Erlenmeyer exhibits a very curious specimen in which there was injury to the radial nerve. The tremulousness, or, rather, interruption to the lines, especially of the up-stroke, is very peculiar (Fig. 1).

It is to be regretted that handwriting following injury to nerves has not been more studied, as much of interest from a physiological, as well as a pathological point of view might be attained.

2. The forms of handwriting caused by injury to the cerebral centres, especially after embolism of some of the cerebral arteries, are of two kinds, which have been described as *mirror-writing* and *agraphia*.

(1) *Mirror-writing.*—At present considerable discussion has been awakened with reference to mirror-writing. Ireland called especial attention to it by his paper on the "Brain" [1] in 1883, and by the republication of the same in his book, "The Blot on the Brain," [2] which he has just published.

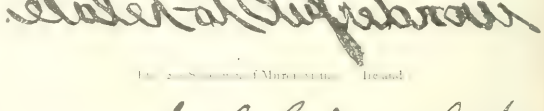

FIG. 2.—Specimen of Mirror-writing. (Ireland.)

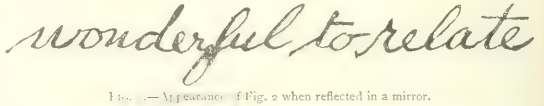

FIG. 3.—Appearance of Fig. 2 when reflected in a mirror.

Mirror-writing, lithographic writing, reversed chirography, the Spiegelschrift [3] of the Germans, is writing which is written from right to left, instead of from left to right, and which when seen in the looking-glass looks like ordinary handwriting. Hughlings-Jackson [4] and Buchwald first discovered it.[5] The latter reported three hemiplegics who wrote with their left hand. He thought it had a pathological signification. Ireland also believes that it is due to the fact that the perceptive centre of the left side of the brain having become injured, the perceptive centre of the right side of the brain gives this idea of writing. Experiments made by himself and Peretti [6] upon school-children and weak-minded, make them announce

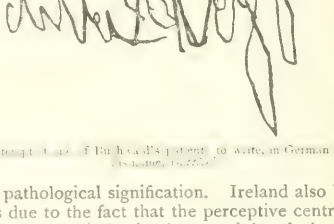

FIG. 4.—Attempt of Buchwald's patient to write, in German characters, his name, [illegible].

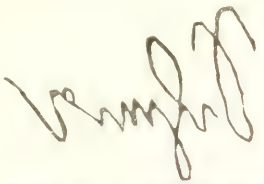
4 Guy's Hospital Reports.
5 Dr. A. B. Judson exhibited before the Surgical Section of the New York Academy of Medicine, November 14, 1885, a specimen of mirror-writing of a girl ten years of age who had had right hemiplegia, which he showed at the Neurological Society after the reading of this paper.
6 Uber Spiegelschrift von Joseph Peretti, Berliner klinische Wochenschrift, 1882, p. [illegible].

the discovery that mirror-writing is more common among such. Possibly there may be cases where there is a true reversal of the impression of the handwriting due to the false perception of the psychical centres. To such cases as these Erlenmeyer proposes the name of Retrographic.



As our handwriting is made to be written from left to right, and only in this direction, it would be impossible for one to write any other than the mirror-writing, if making the letters with either right or left hand in the reverse direction, that is, from right to left. Almost any person attempting this, combining the letters and writing without thought, will find that mirror-writing will be the result. I have had it tried again and again by way of experimentation. Since our writing is done with a centrifugal motion, one can see that in a certain number of

cases, even in most cases, the attempt to write with the left hand would be to write away from the body. The result would be a reversal of the writing as has already been shown. It is much easier to write in this manner, and the writing is more smoothly done for one unaccustomed to using the left hand. It may be suggested that figures, since they are disconnected, would form a good test as to whether the mirror-writing in right hemiplegics was a symptom of the disease. At first sight this would appear to be so. Buchwald in the case of one of his patients (Figs. 6 and 7) shows that some of the figures, especially 3, 5, and 7, were reversed, and that the hook of the number 5 was reversed even after the patient recovered. In experimenting to find out how one would write normally the figures from right to left with the left hand, and without thinking, I found that some of the figures would often be reversed. In a number of times in one person I found that 2 and 4 were very frequently reversed, as also 10.

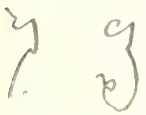


Fig. 7.

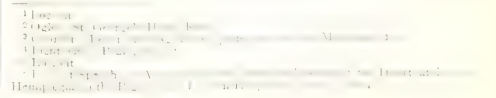
I have therefore arrived at the following conclusions with reference to mirror-writing: First, that mirror-writing may indicate a change in the perception of the nerve-centres of the brain, what Erlenberg would call Retrographia. The patient suffering from this would read the reversed handwriting certainly as easily, if not more so, than the normal. I have only found one mention in the cases reported as to this fact. Ireland says distinctly of an imbecile girl who wrote mirror-writing that she could *not* read it as well. This would be a means of diagnosis between a cerebral mirror-writing and mirror-writing from mechanical causes alone. Second, that from twenty-five careful examinations of the cases on record no indication has been found that the mirror-writing occurred from other cause than a mechanical one, that is, the person writing with the left hand could do so more easily in a centrifugal than a centripetal direction, the former association of ideas and muscular action making this so. Therefore, a person weakened by disease, weak-minded children, and left-handed, would write centrifugally, and if centrifugally, then from necessity the mirror-writing, as all persons would when not exercising care and forethought. The same holds true, though not to such a degree, of figures. The reason lies not in a pathological condition, but in a physiological, namely, that the muscular movements associated with writing are in a centrifugal direction, which makes it easier for one to write, sick or well, with the left hand, unless trained otherwise, in a centrifugal direction.

(2) *Agraphia.*—This subject has been much discussed of late with that of aphasia, first spoken of by Marce[1] in 1856. The name agraphia was suggested by Ogle,[2] who distinguished between the forms—the ataxic and the amnesic. There are a very few cases of agraphia uncomplicated with aphasia on record. It is only recently that the varieties of these two diseases have been analyzed, and that it has been shown that the conducting nerve-paths, sensorial and motor, the receiving centres, visual, auditory, and motor, may likewise come in for their share of trouble. Therefore in agraphia there may be word-blindness, word-deafness,[3] or a volitional motor disturbance resulting in inability to write. The investigators of the subject have also entered deeply into the discussion of the seat of the writing centre in the left hemisphere. The unilateral theory is not so fully endorsed as hitherto, and to the right brain is assigned important functioning power.[4] It is thought that the commissural fibres pass over to the main centres high up above the motor centre of speech in the medulla oblongata.

That these centres, like those of the special senses, with which they are intimately connected, will be more definitely settled as observations multiply with this purpose in mind, cannot be doubted. In consequence of the distribution of the complex act of writing among the different centres the disturbances may be varied; a person may be able to write perfectly and not to copy or write to dictation, or to copy, or *vice versa*. Very few cases of pure agraphia are on record. Almost always the speech centre is more or less involved. Pitres[5] published a case of a patient who, after apoplexy, suffered from agraphia. Speech, understanding of language, and writing were intact; while volitional writing, and writing to dictation were impossible, the faculty of copying was alone preserved. It was unilateral. The agraphia affected solely the right hand; he could write correctly with the left hand, and having so written he was able to copy it with the right hand. This is an uncomplicated case of pure agraphia. Charcot cites the case of a Russian officer who could speak fluently Russian, German, and French. He lost the power of language for a short time; could understand all these, but could only reply in Russian. At the time Charcot saw him he had recovered his power of speech, but was totally unable to write even in his native language. Generally in patients with aphasia and agraphia the power of speech returns first,[6] while the power of writing comes afterward and more gradually. Lichtheim calls attention to the fact that there may be instances of bilateral isolated agraphia, though the distinction has been overlooked heretofore. J. Hughlings-Jackson gives several cases of aphasia associated with agraphia. One of these illustrates well the amnesic agraphia. The case (Fig. 8) is that of a woman, who was able to talk, and only occasionally called things by their wrong name. A striking contrast, as the writer says, is seen between the ability of expression and the written words.

Another case (Fig. 9) shows the ataxic form though at the same time it is combined with the amnesic. The patient, a right hemiplegic, could only swear. Dr. Ham-



mond[1] also gives a specimen of ataxic writing even more characteristic (Fig. 10). The attempt is that of a gentleman to write his name, who, after a stroke of apoplexy, was unable to say more than three words: "speak," "saw my leg off," "certainly."

Fig. 8.—Specimen of Amnesic Agraphia. Shows tendency to repetition of combination of letters seen in handwriting of insane. When occurring in speech called "echo-symptoms." (J. Hughlings-Jackson.)[1]

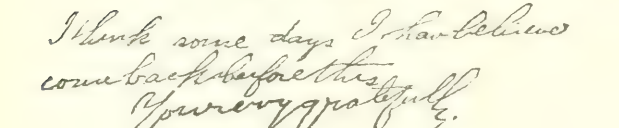

Fig. 11.

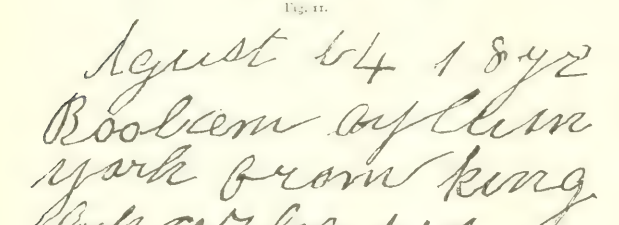

Fig. 12.

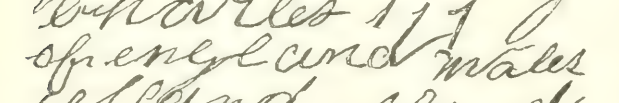

The diagnostic value of the handwriting in agraphia, is in the evidence it gives of the extent of damage done in these cases of hemiplegia to the brain tissue, and also an indication of the location of the trouble, as well as the common service in all localization, the giving hints to clear up the dark, mysterious problems which surround the physiological action of the brain.

3. *Handwriting of the insane.*—As far as the mechanical execution goes in the early stages of insanity there is little which denotes the incursion of the disease, but when patients begin to omit words and to spell badly in their letters, it should excite suspicion in regard to their sanity, and in many instances it is a sign of the beginning of general paralysis.[1] In examining specimens of the handwriting of those afflicted with this disease, its progress is shown by well-marked characteristics. It is the reverse of the progression made in childhood. The scattered pot-hooks and ataxic marks of a child first learning to write are seen in the latest stage, before that the coarse, irregular letters are combined to make words and intelligible sentences, which straggle in uneven lines, the forming of the line as seen in childish writing spoken of by Erlenberg. The first mechanical sign is a diminution of the handwriting, a running of the words together, and either not finishing the final letter or terminating it in an irregular line, or dropping it entirely. A shakiness of the letters is seen throughout. In this early stage frequent under-scoring occurs, and an irregular and plentiful besprinkling of capitals. Bucknill and Tuke remark that patients may recover their handwriting even after the worst stage.

In acute mania there is ample indication in incoherence, but the letters are not forgotten. A consideration of the vagaries of composition would be foreign to this paper. They take curious and diverse forms, a repetition of the letters often occur, as shown in the sample of the writing of the woman afflicted with agraphia (Fig. 8). Sometimes the letters are microscopic in their fineness, and figures and letters intermingle. Sometimes the lines are written across one another again and again, until there appears a criss-cross of unintelligible lines.

4. *Handwriting of cerebro-spinal sclerosis and locomotor ataxia.*—The handwriting of patients suffering from cerebro-spinal sclerosis is characterized by its tremulousness.[2] Hammond gives in his work on nervous diseases an interesting specimen, which exhibits a tremulousness in the lines, especially in the up-hand strokes, which contrasts in an interesting manner with the writing of paralysis agitans. Onimus[3] first called the attention of the profession to the

[illegible] (Pitchaill and [illegible] ters together, and incoherence of composition.

[illegible]

peculiarities of the writing of these patients [illegible] motor ataxia involving the upper extremities. Hammond has confirmed his conclusions.

The phenomena exhibited in the hand writing are similar to those seen in the lower extremities. The changes are shown early when writing with the eyes closed, especially in round letters, c, a, and o, as well as in l and e. They are formed by straight lines, more or less extended, instead of curves. There no longer exists the synergy of muscles. When the disease is further advanced, the writing is ataxic, when the eyes are open, though not so much so as when they are closed; the letters are made with a jerk, and the hand has difficulty in limiting the trace. In p, for example, the line never ends

with a neat termination, and there is an impulse to continue; the pen catches and sputters, and the patient is

often obliged to use a pencil. Later, when the ataxy of the arm is pronounced, the attempt to write results only

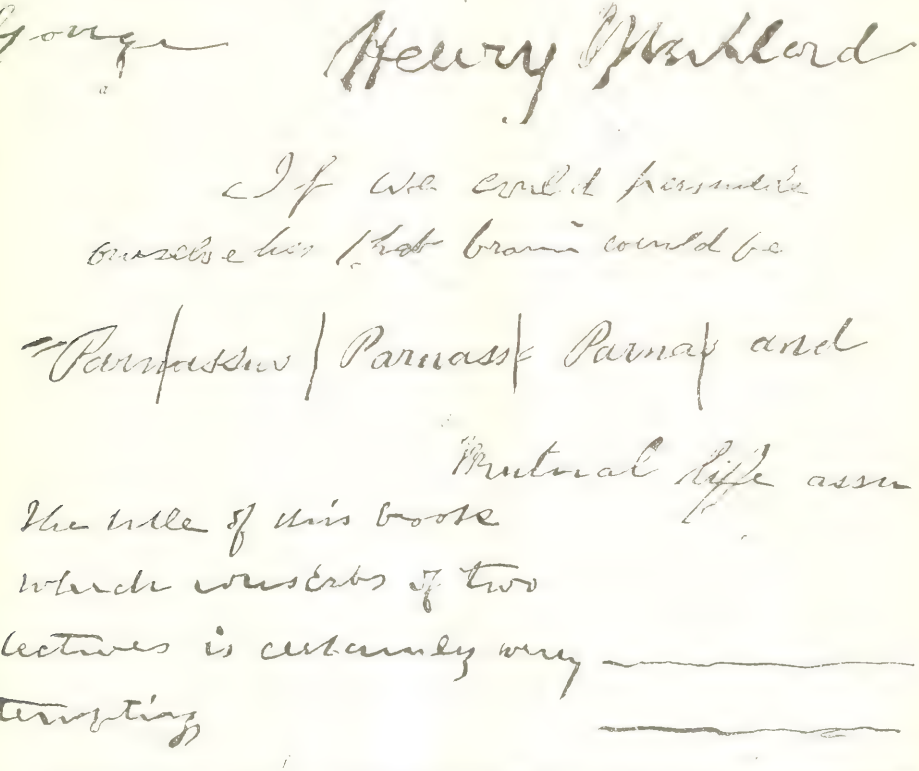

Fig. 1.—Specimen of Writing [illegible]

arm, & tremor and [illegible] also a neuralgic

in unformed traces without order; there is inability to write a single word. It shows the same march of the disease as is seen in the lower extremities.

3. *Functional disturbances of the handwriting.*—Under this head will be included the writing of paralysis agitans and writer's cramp, as might also be that of chorea and hysteria. In the two latter there is nothing of especial diagnostic value. The writing of paralysis agitans shows the tremor in the early stages. Although the handwriting looks normal to the naked eye, a glass will reveal the peculiar character given it by the trembling.[1] The long letters show it more than the others. The tremulousness of the lines becomes more pronounced as the disease advances, and there is a diminution in the size of the letters.

In *writer's cramp*[2] the writing shows many forms of disturbance, and were there no history and the story of the disease could only be gathered from the handwriting, it would be difficult to say whether we were dealing with some of the various forms of tremor, paralysis agitans, progressive muscular atrophy, locomotor ataxia, arthritis deformans hemiplegia, or disease of the motor nerves. A study of the handwriting will, however, reveal the nature of the disturbance, whether with the spastic, tremulous, or paralytic forms, as Benedict names them. Ross[3] thus describes the difficulties encountered in each of these: "In spastic form of the disease tonic or clonic spasms of one or several muscles occur. The spasms are limited to particular fingers, causing an irregular stroke in the writing. The pen must be held in a new and more or less grotesque manner. After a time the spasms become stronger, and are generally tonic in character, affecting usually the thumb and first finger. The thumb and finger may be suddenly extended, causing the pen to drop, or there is a spasmodic action of the opponens pollicis with abduction and flexion of the index finger, so that the pen is rapidly moved away from the paper. At other times a spasmodic flexion of the first three fingers, so that they are pressed tightly against the pen, which cannot then be moved further onward, or there may be movements of pronation and supination in the forearm so that the pen is raised from the paper and moved backward and forward in the most irregular manner.

"In the tremulous form of the disease the hand and forearm, or even the whole arm, become the subjects of well-marked tremors on any attempt at writing being made, so that the pen only makes undulating or angular strokes, and the writing becomes completely illegible. The strokes are coarse and imperfect and unequal, and numerous irregularities and false strokes are to be observed, and in the highest degrees of the affection the writing becomes a mass of undulating and zigzag strokes wholly illegible.

"The paralytic form offers a great contrast to the spastic and tremulous forms. It is characterized by great fatigue and weakness when the attempt is made to write, which vanishes when the pen is laid aside, to reappear as soon as it is taken up."

RECAPITULATION.—To recapitulate, then:

I. Mirror-writing may be, but is probably very rarely, indicative of nervous disease.

II. Of other pathological chirography the two great forms are the ataxic and tremulous. In many diseases these two are intermixed.

1. The *ataxic writing* is: (*a*) Physiological in childhood and with the untutored; (*b*) it is characteristic of alcoholism, cerebral, cerebellar, and spinal affections in which there is sclerosis or other alteration, and the paralytic and other diseases, with loss of voluntary power over the muscles, or of weakness and fatigue of the muscles; (*c*) it is characterized by large letters, often excessive in size, illegible, and extremely unequal and uneven.

2. *Tremulous writing:* (*a*) Physiological in old age; (*b*) caused by trembling of the hand and arm from cold, poisonous substances, as nicotin, tea and coffee, morphine, or alcohol; diffuse multiple sclerosis, rhythmical chorea, paralysis agitans; (*c*) its character varies from an almost imperceptible to a decided waviness of the line, occurring in only a few letters, or in all on up-strokes or down-strokes. It is legible, and the letters are of the same size, and usually small and well formed.

RHEUMATISM IN EARLY LIFE.[1]

By HENRY DWIGHT CHAPIN, M.A., M.D.,

LECTURER ON DISEASES OF CHILDREN AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING PHYSICIAN TO THE OUT-DOOR DEPARTMENT OF BELLEVUE HOSPITAL.

THE purpose of this paper is not to advance new theories concerning the rheumatism of childhood. It has seemed, however, to the writer that this subject has not received sufficient attention, especially in relation to its great importance. While some old and familiar diseases are being diligently restudied in the light of bacteria and micrococci, it may be profitable to call attention to a well-known affection in which no bacillus has been found, but that, nevertheless, is continually and hopelessly crippling children for life in such an insidious form as to be constantly overlooked. The facts, then, that are not always appreciated, may be emphasized by a clinical study of seventy-six cases that have come under my observation. And first it may be well to glance at some of the opinions of different writers concerning the frequency, or even the existence, of rheumatism in early life. While most of the older authors were skeptical as to the occurrence of the affection before puberty, the more recent writers generally acknowledge its existence at an earlier period, but do not insist with sufficient emphasis upon its frequency. In 1875, Jacobi published a paper contending that acute rheumatism in infancy and childhood was frequent and insidious. Meigs and Pepper state that the importance of the subject is not usually appreciated, and that rheumatism in children deserves careful attention not only on account of its frequency and peculiarities, but also on account of its marked tendency to cardiac complications, and of its recently established relations to chorea. According to Senator, youth and early manhood are especially liable to the disease, the favorite period lying between puberty and the age of thirty, that from the thirtieth to the fiftieth year coming next in order; children under four are scarcely ever attacked. Longstreth considers that from puberty to the age of thirty or thirty-five years' acute rheumatism is a very common disease, but that in early life rheumatism in any form is a rare affection. J. Lewis Smith says that rheumatism was formerly supposed to be rare in children, but more accurate observations show that it is scarcely less common during childhood than in adult life; it is frequently overlooked, especially under the age of six or eight years. D'Espine and Picot state that rheumatism is an affection less common among children than adults, and is rarely seen under five years. Descroizilles considers that while rheumatismal affections are not so frequent in children as in adults, yet they are less exceptional at an early age than was the opinion of the older pathologists. While not a few cases are found in children's hospitals, one would recognize them still more frequently if many of the little invalids were not treated at home by reason of the relative benignity of the symptoms which they present. Among 4,908 cases of acute rheumatism admitted during fifteen years to St. Bartholomew's Hospital, London, only 1.79 per cent. were under ten years, and 8.1 per cent. were between ten and fifteen years.

Henoch finds the majority of cases of acute rheumatism in childhood occur between the ages of nine and

thirteen years, while it is much rarer between the ages of five to eight years. Howard states that acute articular rheumatism is, *par excellence*, an affliction of early adult life, although no age is entirely exempt. Most authors, then, while of the opinion that youth and early adult life are the periods most frequently attacked, are not inclined to consider the affection as comparatively very frequent during childhood, although not denying its possibility. Yet I think that any child's clinic, if carefully studied, will produce relatively as many cases of rheumatism as are found in adult classes, but of a different type.

Among 76 cases that have come under my observation, the following are the ages: six months, 1; eleven months, 1; twenty months, 1; three years, 1; four years, 2; five years, 4; six years, 6; seven years, 3; eight years, 11; nine years, 9; ten years, 5; eleven years, 8; twelve years, 7; thirteen years, 9; fourteen years, 4; fifteen years, 2; seventeen years, 2.

During infancy the affection is not very common. Henoch treated an infant of ten months with well-marked rheumatism, complicated with broncho-pneumonia and pleurisy. Senator states that Widerhofer observed the disease in a baby twenty-three days old, and Stäger met with it in an infant four weeks old. My youngest case occurred in a baby of six months, whose father was rheumatic. The backs of both hands were swollen and inflamed for several days, accompanied by a general urticaria. In another case, a baby of eleven months had always been healthy until the right elbow-joint became swollen and inflamed; in a day or so the right knee was involved, and next the right side of the neck became enlarged and painful. The appearance of the joints was exactly like that observed in the adult. There was no cardiac complication. The family lived in a canal-boat, and the father had been subject to rheumatism. In another instance an infant of twenty months was taken with vomiting and fever on Saturday evening. The fever continued on Sunday, and she seemed disinclined to move. Temperature, 101¼°. On Monday morning the big toe and ankle of the right side began to swell and grow painful, followed in a few hours by the corresponding parts of the other limb. The affected joints were very slightly reddened. Recovery took place in about a week. The father had been subject to rheumatism for eighteen years.

The following typical case, taken from my note-book, brings out the points to be noted in this paper: Hester L——, aged twelve years. Her grandfather has had rheumatism, and the father is subject to pains in his ankles. The only diseases the girl has had are measles and varicella. Three years ago she had an attack of rheumatism, involving first the knees, then the ankles, shoulders, and hands. She was confined to bed for two weeks, and during this time was much frightened by a Board-of-Health physician calling to vaccinate, when her mother was out. Upon recovery from the rheumatism she was seized with a general chorea. Two weeks ago she had a second attack of rheumatism, involving only the ankles, attended by little pain and very slight swelling, but followed likewise by a general chorea. This time there was no history of fright or any nervous shock. The child has a mitral regurgitant murmur and is hydræmic. Her mother says she is subject to frequent attacks of painful and swelled tonsils.

An analysis of these various symptoms, shown in the comparative study of seventy-six histories, may prove of interest. And first, for heredity as a causative factor. While the exact nature and conditions of hereditary influences are not known, it seems to me an undoubted fact that some state of the system is transmitted from parents to children that will favor the development of rheumatism upon the presence of an exciting cause.

It has been argued that rheumatism is not hereditary, because, if so, it would appear earlier in life. The direct physiological heredity that manifests itself so early in life in the congenital variety of syphilis is different from the heredity that tends to develop rheumatism. In one case the actual disease itself has been transmitted; in the other, only the tendency to disease.

No matter how favorable its environment, the infant who has syphilis congenitally will develop the lesions of the disease in time; the child of rheumatic parents, on slight exposure, may develop rheumatism from a state of the system favorable to the complaint, but may escape if the exciting cause be absent.

A careful study of statistics in reference to the frequency and descent of rheumatism in families should enable one to reach correct conclusions in this matter. It seems to me that what Longstreth calls statistical heredity is just as valuable in showing tendencies to disease as physiological heredity is in predicting future constitutional lesions. A pretty certain proof of hereditary tendencies in rheumatism is seen in the trouble frequently developing as early as it does, before the hardships and exposures of adult life. Some exciting cause, as slight cold, brings on the rheumatism after the more careful nursing of infancy and very early childhood is abandoned. The practical deduction from such a consideration is, that when parents are rheumatic extra care should be taken in the raising of children to prevent an onset of the affection.

In looking over my note-book I find I could get distinct histories of rheumatism in the family in the following instances: Fourteen children had rheumatic fathers, and 13 others had rheumatic mothers; in 6 cases both father and mother had suffered from rheumatism; in 3 children both grandfather and father had suffered; in 1 case the grandfather alone; in 2 cases brothers, and in another case a sister, gave accounts of rheumatic attacks. Many more cases, not enumerated, gave strongly presumptive evidence of rheumatism in the family, but were not counted because of some uncertainty.

Thus, some parents had valvular disease, but denied ever having had rheumatism; in many instances a friend of the family brought the child, and could not tell whether its parents were rheumatic or not. In the great majority of cases in which I could get a full and intelligent history, one or both parents had suffered from rheumatism.

In early life rheumatism appears to attack girls more frequently than boys. I do not know of an explanation for this peculiar fact, as one would suppose that boys, being more exposed, would suffer more frequently. Among 69 cases tabulated by Goodhart, 42 were in girls and 27 in boys. Out of my 76 cases, 50 were girls and 26 boys. The peculiar and evanescent nature of the lesions, together with their shifting character, make it difficult to get an accurate history of the parts of the body exclusively affected in children.

In the majority of my cases some parts of the lower extremities alone were affected, and most of the instances in which the upper part of the body was attacked, were secondary. In 43 cases the lower extremities alone were invaded; in 23, some part of the upper as well as the lower, and in 3, some parts of the upper extremities alone were attacked. When the lower extremity was involved, the knees were affected oftenest, as noted in the histories of 40 cases; the calves of the leg are mentioned in 20 cases, the ankles in 17 cases, and the thighs in 18 cases. In the upper extremities, the elbows are noted as being affected in 10 cases, the shoulders in 7, the neck in 4, the wrists in 4, and the hands, principally on the backs, in 8 cases. Some children complained of general soreness and pains all over the body, without being able to locate them in any one particular spot. Many had pains of a more or less severe, irregular nature in various parts of the back and chest, and I have come to regard such manifestations as very suggestive of rheumatism, irrespective of pleurisy and cardiac inflammation. In 2 cases the plantar surface of the feet bore the brunt of the disease. The manifestations of rheumatism, as studied in these children, were very light as re-

gards the joints and limbs, with some exceptions. Swelling of the parts affected was always very slight, and in a majority of the cases entirely absent; when present, it would quickly disappear. Pain was likewise not very severe, and was noticed principally on exertion. In children old enough to give an intelligent description, there was frequently a complaint of stiffness and soreness upon exercising, rather than actual pain. With the exception of perhaps ten or fifteen cases who were confined to bed, the children were allowed to go about as usual, although constantly complaining. In most of the cases there was no redness or other particular sign of inflammation at the part affected; there was likewise, as a rule, little or no rise of temperature when the cases were brought to my notice. Fasciæ and muscles about joints were apparently largely affected. Many of the histories showed more than one attack of rheumatism. The tendency to a repetition of the trouble was shown as follows: In 22 cases there had been two attacks; in 4 cases, three attacks; in 1 case, four attacks; in 2 cases, five, and in another, 6 distinct attacks. It happened in many cases that it was impossible to get an accurate history of the number of seizures, as the parents would say that for one or two years the child had complained of pains every few weeks. Some of the children, indeed, seemed so saturated with rheumatism as to be complaining more or less all the time. A very general feature in these cases was the presence of marked hydræmia. Nearly all the children that I have treated for rheumatism have been in this condition, and it forms an important factor both in diagnosis and treatment.

The absorbing interest in connection with the study of rheumatism in early life relates to the heart. According to Senator, the younger the patient the greater the risk of the heart becoming affected, as this organ is implicated in fully one-third of all the cases occurring before puberty. Thus Vernay found that of 22 cases between the ages of fourteen and twenty, only 1 escaped endocarditis. D'Espine and Picot found in 47 cases of rheumatism in children only 10 cases in which the bruit of the heart was perfectly normal, and state that Vohsen found cardiac complications in 9 out of 20 cases. These authors further observe, that while it is not rare to see in children an endocarditis or a pericarditis with a very light affection of the joints, such inflammation may likewise accompany a simple torticollis. Descroizilles states that at an early age the central organs of the circulation have a particular aptitude for attack. He likewise states that Vogel, Steiner, and Roger agree that a considerable number of the lesions of the endocardium and pericardium have no other origin than rheumatism, affecting first the joints or muscles. Out of 76 cases that I have examined under seventeen years of age, 26 have had organic valvular disease of the heart. Of the 26 cases, 18 had mitral regurgitant murmurs; 2 had double mitral combined with double aortic murmurs; 2 had mitral regurgitation with double aortic murmurs; 1 had mitral regurgitation and obstruction; 1 had mitral regurgitation with an aortic direct murmur; 1 had a mitral obstructive murmur, and 1 had endocarditis, myocarditis, and pericarditis. Thus one-third of my cases gave evidences of organic heart disease when I saw them—the same proportion that is quoted above from Senator. But this number does not, I think, represent all the cases in which the heart was affected by endocarditis in these children. The heart is probably more often slightly attacked by endocarditis without leaving a permanent lesion than is supposed in the mild attacks of rheumatism from which children suffer. Palpitations and wandering pains over the cardiac region are very common in these rheumatic attacks, and doubtless sometimes represent an inflammation in which there has not been sufficient exudation to produce a bruit. I have likewise seen cases in which a murmur produced by an acute endocarditis has disappeared some time after the inflammation has abated. Thus, a boy of eight years was brought to me with rheumatic pain and swelling in his left elbow; the cardiac sounds were normal. The trouble left the joint, and in a week or so he began to complain of pain over the heart. An examination revealed a loud systolic murmur, heard plainest at the apex, and a diagnosis of acute endocarditis was made. His mother nursed him carefully, and now, about a year after the attack, the bruit has entirely disappeared, and the boy enjoys good health.

As far as I have noticed, acute endocarditis in children often appears to cause less local and constitutional disturbances than in adults, and thus is more liable to be overlooked. It is surprising how obscure the symptoms of acute heart trouble may be in children. Bouillaud states that in early life the heart comports itself like a joint with reference to the rheumatic poison. This simile is exemplified by the fact that in some attacks of rheumatism the cardiac inflammation may precede by several days the articular.

A girl of twelve years that I examined began her illness by some pains in the heart, shortness of breath, and a feeling of prostration. When this had continued a week she was seized with pains and slight swelling in the knees, ankles, and elbows, affected in the order named, the whole trouble lasting three weeks. She had a distinct mitral obstructive murmur, with accentuation of the pulmonic second sound.

An endocarditis is not infrequently the only lesion manifested in the rheumatism of children. A number of cases coming under my observation have exemplified this fact. The following history is a fair example:

A girl, fourteen years of age, whose mother is rheumatic, has never had any illness except measles and pertussis. She came to me complaining of pains and palpitations of the heart, loss of appetite, and failure of strength. Occasionally a little blood was coughed up. On examination mitral regurgitation was heard, without lesions of the lungs. There was no affection of the joints or muscles at any time.

In other cases the heart will be attacked some time after rheumatism of the joints, and at the time constitute the only manifestation of a rheumatic attack. Thus, I have recently examined a boy who suffered three months ago from an attack of rheumatism in the knees and calves of the legs, which were sufficiently painful and swelled to confine him to bed. He recovered without any trouble in the chest. Several weeks ago, after exposure to cold, he was seized with some distress about the heart, without pain in any other part of the body. As a result, there is now sufficient mitral incompetency to cause dyspnœa upon much exertion.

In most of the histories of valvular disease, as nearly as I could get at the facts, the cardiac affection seemed to come on after several attacks of rheumatism. It appeared as if the heart finally succumbed, unable to resist repeated attacks, just as one joint after another will yield to the disease. A girl, six years of age, first had rheumatism in the thighs, lasting a week. Some months afterward she had an attack involving first the feet and next the hands. After another interval of months she had a rheumatic seizure in the knees, followed by slight pain and constriction in the chest. When I examined the heart there was some enlargement and a mitral regurgitant murmur.

In another case a girl, eleven years of age, who had previously been healthy, began to complain at intervals of slight pain and stiffness in the knees, calves, and ankles, principally on exertion. No particular attention was paid to the affection, and she was sent to school as usual. After about eight months, during one of these attacks, she was suddenly seized with distress in the chest, followed in a few days by intense dyspnœa. Physical examination showed pericarditis. Death took place in a month from heart failure and œdema of the lungs. At the autopsy I found extensive endocarditis, involving

both the aortic and mitral valves, together with myocarditis and pericarditis. The mitral valves were retracted and partially bound down, and the aortic valves were covered with fine fibrinous vegetations. A general myocarditis was shown by a fatty condition of the heart-muscle, and the pericardium was adherent to about half its extent; where free, both surfaces were covered by thick layers of fibrin. I presented the specimens before the Pathological Society as exhibiting a case in which all the structures of the heart, with its envelopes, were completely destroyed after repeated insidious attacks of rheumatism that were so mild as to pass for growing pains. The lesson to be learned from these cases is that an early diagnosis should be made, and immediate, vigorous measures taken to combat the first manifestations of rheumatism in children, fearful that, although the heart may escape the first attacks of these mild pains, it may suddenly and unexpectedly become affected by an equally light manifestation of the disease. Goodhart states that it is impossible to say what proportion of heart cases occur as the direct outcome of one attack of rheumatism, or how far the damage results from some persistent state which slowly and surely cripples the valves. Congenital heart disease is rare in children, and naturally involves the right side, which is functionally most active during fetal life. Jacobi has called attention to the fact that in children simple hæmic murmurs are very rare. It is difficult to find out comparatively how much oftener cardiac complications of rheumatism are seen in children than adults. Different authorities do not agree as to the proportion of all cases of rheumatism in which the heart is affected. I quote the following from Howard:

"The gross proportion of heart disease of recent origin in acute and subacute rheumatism was, in Fuller's cases, 34.3 per cent.; in Peacock's, 32.7 per cent.; in Sibson's, 52.3 per cent.; in 3,552 St. Bartholomew's Hospital cases, analyzed by Southey, 29.8 per cent.; in Bouillaud's cases, quoted by Fuller, 5.7 per cent.; in Lebert's, 23.6 per cent.; in Vogel's, 50 per cent.; in Wunderlich's, 26.3 per cent." Of Fuller's cases 58 per cent., and of Sibson's 62 per cent., were under twenty-one.

With reference to the connection between rheumatism and chorea in children I presented some statistics in a paper read before the Neurological Society in 1883. In the histories of 38 cases of chorea given at that time 22 were preceded or accompanied by rheumatism. While it is difficult to determine exactly the relative influences these affections have upon one another, the study of a larger number of cases since that time has confirmed my belief in the close relation between them. It seems probable that the same morbid condition predisposes to both rheumatism and chorea in children, and that they may be different manifestations of the same affection.

Descroizilles says that the lesions engendered by rheumatism frequently propagate themselves to the heart, or better, transform themselves, and choreic convulsions replace the first phenomena. Soltmann, in his article on chorea, quotes Roger, who thinks that chorea and rheumatic affections of the joints, and heart affections, are members of one and the same pathological condition. Therefore, he makes a division into chorea rheumatica, chorea cardiaca, and chorea rheumatica cardiaca, and he is unable to state which process makes the commencement. Often the chorea is primary and the heart affection secondary, or *vice versa*, or the heart affection and the chorea appear at the same time. Again, the chorea may appear first, then the rheumatism, and lastly the heart affection; but generally the rheumatism is first, next the chorea, and the heart affection afterward. In thirty-five histories of rheumatism I found a connection with chorea, generally the chorea following some time after a rheumatic attack, but occasionally *vice versa*. Certainly rheumatic children are extremely liable to develop chorea. I could give many histories exemplifying this fact. In one case I treated a boy, eight years of age, who had six attacks of rheumatism, followed each time by chorea after a short period. There are seven cases in my note-book in which rheumatism has occurred after one or more attacks of chorea. Thus, in a boy, seven years of age, whose father was rheumatic, twitching began on the left side and soon became general. This was followed by rheumatism in the arms and legs. During the next two years he had three more attacks of chorea, but no return of the rheumatism. In another case a girl, nine years of age, with no family rheumatic history, had two severe attacks of general chorea, the latter followed by rheumatism in both thighs, the right shoulder, and neck. I have four instances of cardiac trouble following chorea without any previous rheumatic history. A girl, seven years of age, with no account of any rheumatism in the family, presented herself with chorea of the right side. The heart-sounds were normal, and she gave no history of rheumatism or growing pains. In a few days she appeared again with a loud, blowing murmur at the apex.

Another girl, eight years of age, whose mother had rheumatism, suffered from two attacks of chorea, the second followed by a mitral regurgitant murmur. Finally, I saw a boy, with Dr. Katzenbach, seventeen years of age, who had double aortic and double mitral murmurs, with great hypertrophy, from which he died. There was no rheumatism in the family, but he had several severe attacks of chorea. His mother told me his breathing never seemed right since he began to have the twitching. The nearest approach to rheumatism he had, was some lumbar pain about a month before he died. Parents with rheumatic tendencies may have children who develop chorea instead of rheumatism. As an example, a girl, twelve years of age, whose father had such severe attacks of rheumatism as to cause delirium, suffered a number of times from general chorea. She never had rheumatism nor growing pains. In many of my histories the chorea did not appear until after several attacks of rheumatism. Thus, a girl, eleven years of age, after two attacks of rheumatism, developed general chorea. She had a mitral regurgitant murmur which I was unable to trace as to the time of its inception. There are so many ways in which rheumatism, chorea, and cardiac trouble seem related, that the opinion of Roger as to their essential identity appears probable.

Rheumatism in children seems to have a tendency to attack mucous as well as serous surfaces, especially the throat. It may seem somewhat forced to seek any relation between throat, and especially tonsillar, affections and rheumatism, yet they occur frequently enough to suggest the possibility of some connection besides a mere coincidence. Bruce, in describing the invasion of rheumatism, says that sore throat, which consists in pharyngeal catarrh, follicular tonsillitis, or even acute suppurative inflammation, is remarkably characteristic. Goodhart says there is a growing frequency of assertion that tonsillitis is a rheumatic ailment, generally preceding the attack. Some other writers speak of the same connection.[1] I have fifteen histories in which tonsillitis

[1] [illegible] tarrh, but in many cases it takes the form of acute inflammation of the tonsils. The percentage of cases was about eighty. In some cases the throat and joints are affected simultaneously; and he has met with cases of relapse from acute rheumatism where the primary attack and the relapse have both been preceded by throat symptoms. The sequence of events is of too frequent occurrence to be explained on the hypothesis of a merely casual connection; that is, that a person having, through a chill, or some other cause, had a 'sore throat,' further exposure has brought on an attack of rheumatic fever. He believes that not infrequently amygdalitis is an early manifestation of the rheumatic diathesis, and that by so regarding it we may prevent the further development of that tendency. Bearing in mind the extreme prevalence of valvular affections of the heart, which in the young may generally be traced to fibrinous vegetations having formed on the valves during the attacks of rheumatism, any means which enable us to foresee, and possibly ward off, a disease causing agonizing pain, and often leaving behind it an irreparably damaged heart, are of great value. Early treatment is very important in acute rheumatism. The cardiac complications usually appear early in the case, and when once the patient has been got to bed the danger from that source is much lessened. So firmly is the author convinced of the truth of these facts, that he thinks seriously of a seemingly trivial throat affection, and in all such cases advises his patients to be on their guard against the slightest exposure to cold, and

was present before, at the time, or immediately after the attack of rheumatism. Thus a boy, nine years of age, came to my office with a severe follicular tonsillitis. He was sent home and went to bed. In three days I was sent for and found acute rheumatism beginning in the knees and back of the neck. Again, a girl, fourteen years of age, with mitral disease, whom I had repeatedly treated, had another attack of rheumatism, involving the wrists and shoulders. She was put to bed in a warm room, and, in several days, as the pain was leaving the parts affected, she was seized with an attack of acute tonsillitis. In another case a girl, thirteen years of age, was treated in summer for mild rheumatic pains in the elbows and chest-wall. The affection yielded to salicylate of sodium, but just as recovery was taking place she returned with an attack of acute tonsillitis. In histories of this kind it cannot, of course, be proven that there is anything beyond a casual connection between the two affections; still, the coincidence is such as to warrant further observation. In acute tonsillitis there is very constantly present general soreness and pains through the limbs, with an elevated temperature; hence the idea has been advanced that it is a constitutional disease. If so, it must be allied to rheumatic fever. It is well known that suppurative tonsillitis can sometimes be aborted by large doses of the salicylate of sodium given at the beginning. Dr. Gilbert, in the Louisville *Medical News*, reports a case in which the whole mucous membrane lining the mouth and covering the tongue was attacked with a follicular inflammation during a rheumatic seizure.

Rheumatism in children is occasionally accompanied or complicated by various affections. I could only detect marked evidences of pleurisy in about half a dozen of my cases. In quite a number of instances there were attacks of acute urticaria. Stiffness and contracture of the muscles of the neck are sometimes seen. Persistent indigestion and pains shortly after eating were often present in my cases, together with more or less headache. Rarely the inflammatory action in the joints and fasciæ will spread to the surrounding areolar tissue, and an extensive cellulitis be the result. In a few cases, in rheumatic children, anterior polio-myelitis was accompanied or shortly followed by rheumatism. As far as I have seen it, the rheumatism complicating scarlatina does not differ in its action from the ordinary attacks. It is often attended by endocarditis, but it is said that the murmur developed by the disease often disappears. In one case that I was able to watch, a marked bruit disappeared some time after the attack. Henoch regards the joint affections in scarlatina as due to synovitis rather than rheumatism. Other authorities, on the contrary, consider that the complications of scarlatina involving serous membranes, and even the kidneys, are essentially rheumatic. In one of my cases, a boy, nine years of age, had a marked attack of peliosis rheumatica, involving the legs, while suffering from mild rheumatic pains. This affection is exceedingly rare. R. Clement Lucas reports two cases in the *British Medical Journal*, in which infants were attacked by gonorrhœal rheumatism resulting from purulent ophthalmia. One baby was eighteen days old, and both parents had gonorrhœa; the other was three months old.

To make a diagnosis of an affection that is often obscure in its manifestation, especially where no one symptom can always be taken as pathognomonic, we must depend rather upon a collection of symptoms, one corroborating the other and collectively forming a clinical picture of the disease. Thus carefully studied and sifted, a correct diagnosis can sometimes be made out of vague and unpromising materials.

In recognizing rheumatism in children we must often depend on what Goodhart aptly calls the "composite" of the disease. In regard to the wandering pains, it is evident that a certain limitation and care must be exercised before considering them rheumatic. Simple bruises and sores must be eliminated, also the muscular weariness developed in weakly children by over-exercise, the products of tissue metamorphosis being imperfectly removed by the feeble circulation, with resultant irritation and pain. But rheumatic pains usually go from one joint to another, or from one set of muscles to another, and exist independently of any such factors as injury or over-exercise. A pain that attacks a knee, then an ankle, and next the muscles of the thigh or calf, is almost surely rheumatic, without other manifestation of the disease. Complete or partial disability may likewise be added to the pain in a part, without any swelling or redness. Thus a girl, eleven years of age, with rheumatic pains in the left shoulder and side of the neck, was entirely unable to lift her arm, although no lesion could be seen. There may be repeated, but evanescent, pains attacking a single joint or the fasciæ lining certain muscles. Other considerations will aid in recognizing the true nature of the pain. Thus, inquiries as to whether rheumatism is present in parents; a careful examination of the heart for murmurs and palpitations; the presence of chorea; marked hydræmia and indigestion, may all aid a diagnosis.

While rheumatism in children is more apt to be overlooked entirely than mistaken for other diseases, I cannot help thinking that symptoms referred to malaria in early life not infrequently have a rheumatic origin. Salicylate of sodium at times has relieved cases where quinine failed in my hands. Many of these cases of obscure rheumatism, however, are improved by tonic doses of quinine. A certain proportion of the cases of rheumatism in early life present the typical lesions seen in adults, and then, of course, the diagnosis is easy.

With reference to pathology, the acid theory affords to my mind the most satisfactory explanation of the rheumatism of childhood. The two principal sources of the collection of acid in the system are, first, lactic acid fermentation of certain kinds of food within the intestinal tract, and, second, the formation of sarcolactic and ethylene-lactic acids in muscular tissues as a result of their functional activity. As a matter of fact, most rheumatic children are improperly fed either in quantity or quality, and suffer from acid dyspepsia; also, the action of the skin, the principal emunctory of lactic acid, is checked by cold, from insufficient clothing. While the truth of this theory may not have been proven, it affords the most satisfactory working basis for treatment. Lactic acid appears to be very readily formed in early life from indigestion, and, during the first dentition, results, according to good observers, in the production of rachitis, the incipient stage of which is extremely common. It is not unreasonable to suppose that the same irritant produces the fugitive pains of rheumatism in older children.

Treatment.—In the majority of rheumatic persons the trouble has begun early in life, and, as one attack makes a future invasion of the trouble more probable, it is of the greatest importance to check the tendency as far as possible at its onset. Not only should the slightest suspicion of rheumatism in the child be subjected to careful inquiry and prompt treatment, but in cases of hereditary tendency the possibility of trouble should be anticipated and averted by careful hygienic training. All forms of indigestion and acid fermentation of food must be prevented. Children may sometimes be fed too largely and exclusively upon the saccharine and starchy foods. The condition of the skin with reference to warmth and normal activity must receive the needful attention. Many children would do better if they were clad completely in flannel, the thickness of which can be regulated by the season. If the flannel irritates, let the skin be protected by underwear of thin cotton. Most of the children I have treated at my clinic have had undershirts containing

to seek medical advice on the first appearance of pain in the joints. Brief notes are given of twenty cases of acute rheumatism recently under observation, in nineteen of which the articular affection was preceded by sore throat, and in twelve the heart and pericardium were affected. Reprinted from Progress of Medicine, New York Medical Journal, vol. xxxiii., 1881.

more cotton than wool, and often exclusively of cotton, during the cold, damp weather of winter and early spring. The first complaint of irregular pains on the part of the child should receive attention and investigation by the physician. If there is any proof, by means of a careful diagnosis, that the trouble is rheumatic, keep the children quiet and in a warm place. My treatment has been to start with a laxative dose of Rochelle salts, followed by a mixture containing oil of wintergreen and salicylate of sodium. At the same time the heart should be always carefully examined, and, if there is any evidence of a bruit, the most absolute and continuous rest in a horizontal position be enjoined. Here it is that permanent and fatal mischief may be avoided. In the first place, a child with slight rheumatism is allowed to go about as usual, exposed to all kinds of weather, until the heart becomes affected; then it sits around complaining of pain in the chest for a few days, when its active habits are at once renewed. This is the history I have frequently seen. The slightest consideration will show how fatally damaging bodily exercise must be to an inflamed heart. The difference in activity and strain put upon the heart in standing up and lying down may be the all-important factor in the child's future. It cannot be too strongly emphasized that the first inception of endocarditis or pericarditis must be recognized, so that all the quiet possible can be given the crippled organ. For this, absolute and continuous body rest afford the only conditions. Otherwise degeneration of the heart muscle, dilatation of the cavity, and crippling of the valves will surely ensue. Goodhart inquires, with pertinence and force, whether in the acute peri- and endocarditis of children a two or three months' recumbency is longer than is necessary for the repair of so damaged an organ.

"Is it too much to insist upon, when the future of a just-opening life depends upon it? The surgeon with the diseased joint makes light of a year of rest; yet who has not seen a child after acute pericarditis skipping about at the end of a month or six weeks as if nothing had been amiss?"

The comparison of the heart to a diseased joint is apt, when we consider Bouillaud's statement that this vital organ acts like a joint in the rheumatism of children. I have recently seen a girl, twelve years of age, brought by her mother to the clinic for pains in the knees. The child was pale, sick, and fainting—symptoms soon explained by the laboring heart and rough murmur that indicated an inflammation still in an acute stage. By dragging the girl about at this critical time her heart was being surely and permanently crippled.

There is evidence that if the heart can be rested for several months in every possible way permanent lesions may sometimes be averted after the endocarditis of children. Let the necessity of a quick recognition of the disease, followed by prolonged rest and nursing, be emphasized by the weight and authority of this Academy.

Even when valvular disease is apparently confirmed in children, vigorous efforts should be made to curtail, and, if possible, overcome, the difficulty. In addition to most careful hygienic oversight, the child should be put upon a prolonged course of iron and cod-liver oil. Occasionally digitalis and other tonics may be indicated. All forms of severe exercise or anything adapted to excite the heart must be scrupulously avoided. Under this treatment cardiac murmurs are sometimes lost sight of in children. With healthy growth and nutrition why may not slight exudation on the valves disappear? Children above an early age bear cardiac disease well from the perfect compensation. In many cases there are no symptoms at all.

I have been treating a boy, thirteen years of age, with double aortic and double mitral murmurs for the past two years, and he has never exhibited a symptom referable to the heart. It is a subject for careful inquiry whether, when young protoplasm is recuperative and growth healthy, more of these cases of valvular trouble cannot be overcome, by puberty, with proper treatment and training.

Descroizilles states that it is important to know that bruits and other stethoscopic signs noted in heart trouble disappear in certain cases in children, sometimes at the end of several weeks or months, sometimes at the end of many years.

Facts of this nature have been cited by Trousseau, Jaccoud, Péter, Roger, René Blache, and Meigs and Pepper. At any rate, valvular disease should be recognized as early as possible in children.

Hence the importance of a more careful study of the rheumatism of childhood, as both it and the cardiac disease induced are so frequently overlooked. We then only get the valvular trouble in the adult when compensation is failing and the prognosis bad. Any effort to lessen the large number of these confirmed sufferers is worthy of careful trial. The crippled lives, agonizing dyspnœa, and sudden death are saddening sights to the physician's life. If a single one of these distressing cases can be prevented by suggestions of early recognition and care, this discussion before the Academy will have served a profitable end.

SIZE OF THE HEART IN CHRONIC DIFFUSE NEPHRITIS.[1]

By GEORGE L. PEABODY, M.D.

In venturing to appear before the Section of Practice of Medicine to open a discussion upon this well-worn topic, it is proper to state that it is not the object of this paper to contribute any new theory of the cause of changes in the heart in chronic Bright's disease, nor even to explain why the heart is sometimes affected and sometimes not; but merely to add to the facts that we already possess some personal observations which have been conducted in the post-mortem room during the last eight years. In that time the number of autopsies has been large—so large that it has not been possible, in the intervals of active work, to glean from the entire number all that might bear upon this subject; but in the last few weeks I have carefully reviewed the records of thirteen hundred consecutive autopsies, with a view of ascertaining certain points which, it seemed, might be of interest to the Section. In these thirteen hundred cases there were recorded three hundred well-marked cases of chronic diffuse nephritis. Only those cases were selected for use in this paper in which the evidence was perfectly unmistakable—cases in which usually the prominent naked eye indications of the complex lesions of this disease occurred, such as a granular surface, with more or less well-marked atrophy of the cortex, together with cysts in the cortex, with or without marked decrease in the size of the organs, etc. In some cases, in which doubt could arise from the general appearances as seen by the unaided eye—and these were numerically but very few—the usual microscopical evidences were ob-

[1] Read before the Section of Practice of Medicine, New York Academy of Medicine, January 21, 1886.

tained before the cases were used in the calculations to be presented to you. To be more specific, no cases are included in the three hundred in which the macroscopic appearances were at all doubtful, except such as revealed the well-marked evidences of diffuse nephritis with which we are made familiar by the microscope, such as increase in the intertubular connective tissue, thickening of Bowman's capsules, more or less complete atrophy of many glomeruli, together with fatty degeneration of much of the tubular epithelium and the presence of casts in many of the tubes.

Again, from this list of three hundred, sixty-five have been omitted for various reasons. Of these, twenty-five were cases of amyloid degeneration; eleven occurred in conjunction with aortic aneurisms. Some had valvular cardiac disease; in some the pericardium was adherent, and a few were left out of the calculation for such unusual lesions as cardiac aneurism, congenital smallness of the aorta, fibrous myocarditis, absence of one kidney, congenital or acquired, etc.

It is interesting, in passing, to note that in nearly every case of amyloid degeneration the heart was small in size, frequently smaller than normal, presenting the lesion known as brown atrophy. Moreover, it is very unusual in my experience to find hypertrophy of the heart in any way dependent upon aneurism. Still, for obvious reasons these classes of cases have been excluded from the calculations upon which the conclusions of this paper are based.

In estimating the size of the heart, many difficulties are encountered by the pathological anatomist. If we endeavor to be very exact, and, by measuring the thickness of the ventricular wall, to ascertain with mathematical precision any departure from the normal, we are liable to err in not allowing for the contracted condition of the muscle, which is frequent enough after death, and may cause any heart to simulate a condition of hypertrophy. Again, in the absence of this misleading condition, the thickness of the ventricular wall is not an indication of absolute, but only of relative, hypertrophy. Thus, the size of the cavities, a swell as the thickness of the myocardium, must be taken into consideration. The weight of the heart is said to afford the most accurate indication of absolute hypertrophy; and yet, without due regard to the size and weight, and general development of the body, an accurate knowledge of the heart's weight is of comparatively little value.

It has seemed to me, therefore, that, although it is open to the serious objection that the personal equation is necessarily a factor in the calculation, perhaps it is better, for those who are constantly making autopsies, to rely upon their own judgment, as based upon a multiplicity of observations, in drawing conclusions regarding such complex problems as the size of the heart. One gradually and imperceptibly progresses in his knowledge of pathological appearances, until after mature experience his unbiassed opinion in a given case, formed after due weight has been given to all the various contributing factors, is worth more than conclusions drawn by elaborate application of exact methods of any one kind, such as measurement or weight.

It is important, in this regard, that the opinion as to the size of the heart should be unbiassed by any knowledge of the condition of the kidneys, or, in other words, that the heart should always be examined and its condition recorded before the kidneys are exposed; and this rule has been followed in the cases that are to be laid before you. One more preliminary consideration must be presented to you before the figures are reached. It would be unfair and misleading if you supposed that this investigation has been carried on systematically during all the years that have contributed the facts upon which it is based. Such has not been the case. I have been, however, for a long time impressed with the frequency with which hearts of normal size have occurred in cases of well-marked chronic diffuse nephritis; but many of the cases of this kind were entered in my record-books years before it occurred to me that they were numerous enough for any such use as that to which you are allowing them to be put to-night.

The question of sex, important though it would seem to be in such a calculation as this, has been, however, excluded, because, for obvious reasons, it is of little value in drawing general conclusions as to relative frequency of any morbid conditions from our hospital record-books.

The three hundred cases are subdivided thus with reference to the size of their hearts:

	Cases.
With cardiac hypertrophy	135
Without cardiac hypertrophy	79
With cardiac dilatation, without hypertrophy	21
Omitted from calculation for various causes	65
Total	300

Thus, of the cases referred to, namely, three hundred well-marked instances of chronic diffuse nephritis in all stages, in seventy-nine the hearts were not increased in size. Of these hearts a very few were dilated to a slight extent, and showed, therefore, some decrease in thickness of the ventricular walls, especially the left. Many were distinctly atrophic, exhibiting the condition known as brown atrophy, and some illustrated well the lesion of fatty degeneration.

When we recall that sixty-five were omitted from the calculation for various reasons given above, we are met by the rather striikng conclusion that of the cases tabulated one-third did not exhibit the condition of cardiac hypertrophy. It is proper to remind you that the kidneys in these cases were by no means all *very* small. All, however, were good illustrations of chronic diffuse nephritis, and many of them were of the very small granular variety.

It has been conceded, I believe, that no satisfactory explanation has yet been advanced to account for the hypertrophy of the heart in chronic Bright's disease, unless it be the chemical theory of Dr. Bright, or that of the general arterio-capillary fibrosis, which seems to be steadily gaining ground. But it is beyond question that, with the co-existence of any chronic wasting disease, such as phthisis, the nutrition of the heart may be so lowered in conjunction with the general nutrition as to interfere with and prevent the possibility of its becoming hypertrophic. Accordingly, in view of the seeming disagreement of these results with usually received opinion, it seemed desirable to ascertain what, if any, accessory or contributing diseases were present in these cases; and, as will be seen from the table given below, more than one-third of these apparently anomalous cases did suffer from chronic wasting diseases in addition to the nephritis, such as tuberculosis, including Addison's disease, cirrhosis, abscess, cancer in various regions, etc. Still, this leaves a long number unaccounted for.

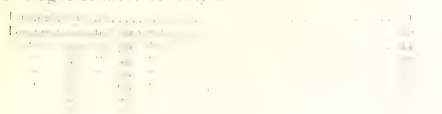
Table of Causes which Contributed to Death in Seventy-nine Cases Mentioned Above

Tuberculosis	15	Pneumonia	4
Addison's disease	1	Disease of liver	1
Cirrhosis	8	Fatty heart	1
Abscess of gall-bladder	1	Peritonitis	1
Ovarian cyst (no operation)	1	Multiple fractures	4
Epithelioma of face	1	Dysentery	1
Epithelioma of neck	1	Burns	1
Cancer of lungs, pericardium, etc.	1	Pericarditis	1
Sarcoma of scalp	1	Laceration of diaphragm	1
Sarcoma of kidney	1	Cerebral hæmorrhage	1
Cancer of stomach	2	Dislocation of knee	1
Pleurisy	8	Pyæmia	1
Fracture of skull	7	Myelitis	1
Stricture of pylorus, not cancerous	1	Pulmonary infarctions	1
Apoplexy	4	Penetrating wounds	1
Pulmonary hæmorrhage	2	Pertussis	1
Sunstroke	1	Intestinal obstruction	1
		Chronic gastritis	1
		No cause except nephritis	7
Total			79

It is interesting to observe in passing that four deaths from apoplexy occur in this list without the existence of cardiac hypertrophy, which is still, I believe, regarded

by some as an essential factor in the causation of that lesion.

The ages of these seventy-nine cases are as follows:



In the cases in which hypertrophy existed, namely, one hundred and thirty-five out of two hundred and thirty-five, the diseases which contributed to death were about equally numerous. I will not delay you by the introduction of another long list. It is sufficient to say that, in direct contrast with those in the previous category, chronic wasting diseases were of extremely unfrequent occurrence, and apoplexy was by far the most important factor, numerically speaking.

Apoplexy was responsible for twenty-two deaths, or more than one-sixth of the total number, a strikingly large proportion as compared with those traceable to the same cause (namely, less than one twentieth of those in the previous category), where there was no cardiac hypertrophy. Pneumonia stood next numerically, and existed in fifteen cases, or one-ninth of the whole. Pericarditis occurred about half as often. Fatty heart came next, with six deaths, and then came a long miscellaneous list of what may be considered indifferent causes.

The only prominent factor in the deaths of the twenty-one cases of dilatation without hypertrophy was pneumonia, which was responsible for one-fifth of them all. It is hardly fair, however, to classify the cases of dilatation by themselves, for the reason that they probably represent hearts that were at one time hypertrophied; and they should, therefore, logically be added to the list of hypertrophied hearts. This would swell the total number of this class to one hundred and fifty-six, a very large, but not unusually large, proportion of the two hundred and thirty-five that form the basis of this brief paper.

One element of doubt which will occur to your minds, and one to which due weight should be given, is the possibility that some of the above apparently anomalous cases may have been cases of amyloid disease in which the waxy changes passed undetected. I can only say that in all cases in which the gross appearance at all suggested the possibility of the presence of this material the usual chemical reagents were resorted to for its detection; and the fact that twenty-five of the sixty-five omitted from this calculation were omitted because they were cases of amyloid disease would lead one to believe that at least the usual proportion of cases of this lesion was recognized by the writer. Still it remains, however, beyond controversy that this lesion is present in chronic Bright's disease far oftener than was formerly supposed to be the case; in many cases to such a very minute extent that the microscope must be employed to render its detection possible; and it cannot be denied that it may have been present here in microscopic amount in some cases in which it was not recognized.

It must also be admitted that the total number of cases is very small for purposes of generalization; hence, the experience of the Section must be looked to for corroboration or correction.

The only important conclusion deducible from what has gone before, and the point in regard to which I hope to elicit testimony this evening, both clinical and anatomical, is that in this city hypertrophy of the heart is less common in chronic Bright's disease than it seems to be in Europe, so far as one can judge by contrasting the results of personal experience here with those which are derived from contemporaneous medical literature.

The *Popular Science News*, says, to obviate the hereditary tendency to disease in the young, "wash them, air them, and *iron* them."

ARE ANTIPYRETICS IN THE TREATMENT OF ACUTE DISEASES USEFUL AND SAFE?[1]

By A. A. SMITH, M.D.,

Interest has been specially awakened in the use of antipyretics in the treatment of acute, and even some chronic, diseases during the past few years. The reduction of temperature has been for many years occupying the attention of physicians, but special attention has been aroused since the publication of the German observers, in the last fifteen or twenty years, in reference to the use of cold in the reduction of temperature. Following this new interest in the subject, new antipyretics have sprung up, and have had many advocates and not a few opponents. At one time quinine had its advocates, and warm ones, too, in the reduction of temperature. With quinine, and the application of cold in its various forms, it was thought possible to so lower the mortality from typhoid fever, and prevent the complications and sequels, as to put in the shade all former plans of treatment, and practically to make it one of the most benign of diseases. This feeling extended to American physicians, and the cold-bath treatment received the sanction of eminent teachers and practitioners. This was but following the teaching of Brand. In 1851, in his first publication, he says: "If typhoid fever is treated from the commencement by cold water, there is in general nothing to fear, and even in cases the most grave, one may yet many times obtain cure by cold water."

Hear him again in 1863: "Every case of typhoid fever treated regularly according to my method takes on a light character, and almost never terminates in death, so that in fact we may say that clinical medicine is in condition to preserve with certainty the lives of all patients entrusted to its care."

And again in 1868: "The treatment by cold baths, methodically employed from the commencement, gives a success positively assured, and always enables one to ward off death."

A French physician of Lyons has summed up Brand's works in these words: "Every case of typhoid fever, treated regularly from the commencement by cold water, will be exempt from complications, and will get well."

When Liebermeister added his name and statistics to those of Brand, it seemed but natural that the medical world should be captured by this plan of treatment. Very quickly the cold bath came into use in this country, following the Germans, as we were formerly in the habit of doing much more than now, and much more than we shall probably ever do again, at least in the way of treatment. What is the result? The plan has been tried, and I venture the statement that to-day not one-quarter of those who were formerly its ardent advocates use it to any great extent. This is not due to the fact that other agents have taken its place, although I must admit this may be true to a certain extent. It is due, it seems to me, to the fact that the treatment as formerly advocated and used was under certain circumstances attended with danger. The application of cold, especially in the form of the cold bath, is an agent which requires great care and good judgment in its use. If properly used, and in properly-selected cases, it seems to me to be an agent capable of doing much good. If used indiscriminately, simply because the thermometer indicates a high temperature, and without regard to all the accompanying circumstances, it may not only do harm, but may be responsible for a fatal termination.

A high temperature simply does not constitute all the danger from a given disease. One patient will tolerate for a long time, and even quite comfortably, a temperature which in another would be accompanied by a train of morbid symptoms in themselves indicating danger. And yet, according to the advocates of the cold-

[1] Read before the Section [illegible] of the New York Academy of Medicine [illegible]

bath treatment, both patients must be treated in exactly the same way. Both must have the temperature reduced by the bath to a certain point regardless of the other effects produced. It has not been proven that high temperature is responsible for the changes which occur in some of the viscera and are found in them after death. It is much more likely these changes are due to the particular poison which produces the fever. In order to determine the usefulness and safety of cold baths in hyperpyrexia from any cause, many things are to be taken into consideration, and this remark may apply to all antipyretics. If a high temperature can be reduced safely, it is fair to presume it is useful. We must consider the general condition of the patient, the stage of the fever, the effects of the first few baths—especially the effects on the nervous system—and the effects on the cardio-vascular system.

If, after the patient is placed in the bath, and the temperature is reduced to, say, 101° F., and then placed in bed, he becomes more quiet, and less delirious (if he has had delirium); if he breathes more easily and less rapidly; if his heart's action becomes more regular and forcible, and the intensity of the first sound is increased; if he falls asleep, and the skin feels moist, he certainly is receiving benefit from the bath. If, however, the extremities remain cold for some time after the bath; if the lips are blue, and the countenance has a deathly hue; if the heart's action is more feeble, and the pulse more irregular, the respiration more rapid and sighing, then, it seems to me, the baths should be discontinued. The stage of the disease at which they would be contra-indicated is an important matter. Taking typhoid fever as a type of the long-continued fevers, I should say, in a general way, that the baths are contra-indicated after the tenth or twelfth day; and, taking pneumonia as the type of short-duration fevers, they are contra-indicated after the third or fourth day, in each case depending somewhat on the condition of the patient. Fever in advanced age contra-indicates them. They are contra-indicated in cases with heart enfeebled from organic disease. But the dangers I have referred to are not the only ones in connection with the cold baths. Congestion of the viscera may, in many instances, be attributed to the baths. I admit the great liability to error on this point, because in all continued fevers there is tendency to congestion of the viscera, more so in some than in others, and much more so in some seasons than in others.

It is rarely necessary to resort to the cold baths for the production of antipyrosis. In very, very rare instances would I advocate the use of the cold bath. I believe all the good to be obtained from the bath can be obtained by milder and less objectionable methods. Cold sponging, wet pack, ice to the head, the cautious and short-time use of the cold coil, and the careful use of ice-water rectal injections, will, in the very large majority of instances, accomplish all that the bath does in the way of good, and are attended with the minimum degree of harm. The greatest benefit, it seems to me, in the cold applications, is not the reduction of temperature, but is due to the profound modification in the functions of the nervous system (especially the vaso-motor). It is not always agreeable to patients (if they have their senses sufficiently to recognize distinctions) to have cold applied. Especially is this so with children. But very few patients will object to the application of tepid water by means of sponging, or cloths, or the wet sheet. It has seemed to me I have succeeded in even reducing the temperature more decidedly by the tepid applications than by cold ones. Certainly, the effects on the nervous system are, as a rule, more beneficial, and these beneficial effects on the nervous system always affect favorably the progress of the fever. Some observers have even gone so far as to assert that almost all the beneficial effects of baths, whether cold or warm, are due to the restoration of the functions of the vaso-motors in the cutaneous capillary network which are so profoundly disturbed in fevers. If this be true, then the tepid applications ought to influence the progress of the fever more favorably than cold ones.

But I have only touched one class of antipyretics, the refrigerants and the opposites.

Quinine in small doses increases the strength of the circulation; just how, we do not know, unless it be by its stimulating effect on the nervous system.

In large doses it diminishes the blood-pressure, by weakening the heart, and partly by paralyzing the vaso-motor centre, thus causing dilatation of blood-vessels.

The heart's action is weakened by large doses of quinine, from its action on motor ganglia, and probably also on the muscular fibres of the heart itself. In a discussion before the New York Clinical Society, two years ago, I raised my protest against the large doses of quinine in certain stages of fevers, and in any case with cardiac enfeeblement, as being possibly dangerous, and need only refer to such possibility here. Then we have the salicyl compounds—salicylic acid, etc., and the aromatic series, as represented by kairin, resorcin, thallin, hydroquinone, etc. And the latest, a nondescript, antipyrin. It is an agent which thus far gives better results than any other. It will reduce temperature in almost every case. It has already, with many, entirely displaced cold and quinine. In some instances it produces nausea and even vomiting, and occasionally cardiac depression, but these unpleasant symptoms have been produced only by very large doses. During my early use of it I followed the plan suggested by the German observers and gave it in large doses, thirty or forty grains every hour, until there was a decided fall of temperature. Now, I find it necessary only to give ten or fifteen grains, ordinarily, to reduce the temperature two or three degrees. On account of this tendency to nausea and sometimes vomiting, and occasionally cardiac depression, I soon fell into the habit of always giving a small quantity of alcoholic stimulant with each dose. Of late, I rarely ever see any unpleasant symptoms from its use. In children, I have observed sometimes a marked paleness soon after it began to produce its effects, but even in such cases a small quantity of stimulant quickly overcomes this unpleasant symptom. It can be given by the rectum, and by hypodermic injection. The objection to its use by hypodermic injection is that it gives much pain. I have used it in a large variety of cases, and consider it by far the most useful and the safest antipyretic yet discovered, if used in not too large doses, and if in connection with its use cardiac stimulants be given when there is any suspicion of cardiac enfeeblement. Whether it favors the tendency to visceral congestions remains to be proved. It seems certain that any antipyretic used to the point of producing great variations in temperature might produce unfavorable symptoms, visceral engorgements among the rest. If we would always resist the temptation to cause too great a fall of temperature, even though it be high, it seems to me we would be more likely to produce good effects and less likely to do harm.

Some Good Advice.—"Sound physiology must be the basis of sound practice"—a fact long recognized in Scotland, where physiology has always been taught as "The Institutes of Medicine." "Nitrogenous waste in the blood is the root of many evils." "Treat the heart as you would your horse: when the roads are heavy feed it well, else you may have a breakdown in a dark night on a miry road." "In lung disease death comes through want of air; therefore, beware of opium." "In painful abdominal diseases death comes through nervous shock, therefore hold on by opium." "Above all, beware of looking at a sign-post instead of looking at the road. If you find sugar or albumen in the urine, do not bolt off with the idea that your patient is fatally ill of diabetes or Bright's disease—that is to look at a naked post and see nothing at either side. Study your *patient*, not merely his *urine*."—*Fothergill.*

"IS ULCERATIVE ENDOCARDITIS ALWAYS A SPECIFIC DISEASE?"[1]

By T. E. SATTERTHWAITE, M.D.

An answer to the question "Is Ulcerative Endocarditis always a Specific Disease?" involves the entire subject of endocarditis, and I will therefore proceed at once to give my definitions of that disease in its various forms.

Through the irritative action of certain animal poisons there is set up within the substance of the cardiac valves, or in their annexa, certain inflammatory or degenerative changes, by which the tissues become swollen and infiltrated, chiefly with cellular and fibrinous exudates, the latter often undergoing molecular disintegration and giving rise to ulcers, upon which there may form, at a later stage, papillary or villous excrescences, and even membranes like those of diphtheria. Sometimes the new products calcify, either alone or with the original tissue; occasionally pus is intermingled with the deposits.

These alterations of the normal structures lead to a multiplicity of secondary phenomena in other organs of the body.

Endocarditis, in any form, is rarely produced by an injury, but in fully one-third of the cases we recognize certain antecedent conditions that are associated in our minds with the etiology of the disease, and the most prominent is acute articular rheumatism. Sometimes the two diseases occur together; probably not so often as we once thought. Sometimes the heart-lesion follows. Other, but much rarer, antecedent conditions are the puerperal state, scarlatina, measles, dysentery, and typhus; but how close the alliance between these several diseases and the one we have under consideration is a matter of some uncertainty. It is commonly said that pyæmia is one of the precursors of endocarditis; personally I have never known them associated together. In about fifty per cent. of the cases the cause remains unknown, although searching inquiries are instituted. But we judge from analogy that the disease is due to a poisonous condition of the blood; possibly to a prolonged high temperature, which has been thought by some to be competent to produce it. There seems to be evidence that tuberculosis also is occasionally the cause. Of this I have no personal knowledge. I do not include senile thickening of the valves among the inflammatory changes.

As for the locality, I am inclined to think that there is no very strict rule in reference to the valves that are elected. It is commonly thought that the left side of the heart is most frequently attacked in extra-uterine line, while the right is involved in the congenital disease. In my collection of forty-eight cases the aortic was somewhat more frequently diseased than the mitral; in twenty-six cases both aortic and mitral were affected; the tricuspid was never the only valve diseased, and only in four cases, always in association with two other valves; the pulmonary was only affected three times, and also in association with two other valves.

There seems to be no doubt that patients seldom suffer much from the simpler forms of endocarditis in their early stages. They often complain of some precordial pain, though even these symptoms may be due to an associated pericarditis, the irregular action of a hypertrophied heart, or pulmonary complications. In a large number of cases there is a noteworthy frequency of the pulse, which, however, is lessened when compensatory hypertrophy has been established—a pulse of 120 to 140 is not uncommon at first. Dyspnœa, orthopnœa, and palpitation also are of pretty regular occurrence. But it is the accidents and complications that are most dangerous to life. In a disease that in nine out of ten cases lasts for years (sometimes twenty, and thirty, and even more), it is natural that these accidents should occur; and we find them in the shape of infarcts in the kidneys, lungs, spleen, or brain, etc., in one-third of the patients. In the great majority they do not cause death—and yet it is these embolic phenomena that often produce the remarkable attacks of chills and fever that puzzle the attendant, because the exacerbations often occur, for some unknown reason, with a remarkable periodicity; but it need not be supposed that such peculiar attacks indicate a septic condition or any specific complication. They occur equally well when the infarcts are benign in character.

It is, however, these secondary phenomena—such as an embolic pneumonia, which only attacks portions of a lobe, never the whole lobe; the enlarged and tender spleen; and bloody urine, with albumen and casts—that should turn the physician's attention toward a possible cardiac disease, even if the physical signs and subjective symptoms have not suggested it.

But probably the most important complication is chronic diffuse nephritis, which stands in close relation to the main etiological factor, viz., acute articular rheumatism; for I have found the latter to precede the former in from forty to eighty per cent. of my cases. It is not strange, then, that about one-half of the cases of endocarditis die of uræmic poisoning in one of its many forms; either through cardiac or respiratory failure, laryngeal spasm, and œdema of the lungs, due to a suspension of the several functions; rather than to cerebral embolism, pulmonary infarcts, or secondary abscesses.

It follows, as a premise from what has already been advanced, that there is some tendency toward cure, even in destructive or deformative endocarditis; and, indeed, the process of cicatrization of the valvular cusps is often a very perfect one, so far as the healing of the ulcer is concerned. Naturally there is some loss of substance, and often a marked deformity.

But while I have thus briefly alluded to the acute and chronic forms of endocarditis, I have left for consideration a variety that has received the names malignant, infectious, diphtheritic, plastic, mycotic, etc., by a certain class of persons, and with these I wish to join in giving it a separate entity. Infective or suppurative endocarditis, as I would call it, rather than malignant or ulcerative, etc. is a comparatively rare disease, if we wish to view it from the narrow standpoint that I think is the only safe one., Pathologically, it is distinct from the others, in that it produces peculiar infarcts which have no tendency toward resolution, but rather in the direction of diffuse abscesses. I offer two such cases, and one that is possibly doubtful, as my contribution to this topic.

Case I.—Infective or suppurative endocarditis. J. C. A——, colored, aged forty-six, was admitted to St. Luke's Hospital, November 5, 1878. He was first taken sick on October 25th; had never before been seriously ill. He first experienced pain in his left knee, and about that time had chilly sensations, followed by headache, backache, and some fever. He took to his bed, where he remained until removed to the hospital. On admission there was found to be pain in the left side of his back, and in his left leg. His left wrist also was swollen, tender, and intensely painful; no fever, but great prostration. On November 28th, after showing no signs of improvement, he passed blood per rectum. Temperature was then found to be 102.4°. Probably there had been an evening rise of temperature for some time; it remained between 101° and 102° until December 3d, when further weakness, trembling of the masseters, and subsultus developed. Toward the end his temperature rose to 104°; pulse to 116; respiration to 46. At post-mortem examination the heart was not found especially hypertrophied, as would have been the case in old endocarditis. At the aortic orifice, beneath one of the cusps, was a verrucose growth the size of a small chestnut, while the valve itself was ruptured. On removing the brain, collections of pus were found in the meshes of the pia mater. At the wrist the first row of carpal bones was found necrotic. Duration of sickness about six weeks.

Case II.—Infective or suppurative endocarditis. The

[1] Read before the Section in Practice, New York Academy of Medicine, December 15, 1885.

history of the case and the specimens were sent me by Dr. Dorning, of the house staff at St. Francis Hospital. A patient of alcoholic habits, aged forty-one, was admitted to the hospital in November of 1882. It was said on his admission to the hospital that he had contracted a lobar pneumonia on October 30th. The sickness was characterized by high temperatures, but no cardiac murmurs were at first detected. Later on this point did not receive much attention, as other and apparently more important conditions obscured the cardiac disease. At post-mortem examination the aortic cusps were found extensively diseased, each segment exhibiting vegetations, while one carried a growth the size of a hickory-nut and was ruptured and ulcerated. An abscess was also found in the course of the coronary artery, and a sinus led from it to the fungating mass in the aortic valve. The spleen contained an infarction. Duration of illness about five weeks.

Case III.—Infective or suppurative endocarditis. A gentleman of this city was taken sick with an attack of fever that confined him to his room for four or five days. He then felt better and went down-stairs, but soon returned and took to his bed. During the first two weeks of his attack the temperature ranged from 98° to 100° F. His pulse also averaged from 140 to 150, sometimes reaching 160. During the last two weeks of his life it had a wider range (120 to 150), but the temperature remained higher (from 102° to 105°). At an early period the diagnosis of obstructive endocarditis was made out. The respiration was never embarrassed, except when the patient sat up. There was never any impairment of motion or sensibility; nor did he experience any pain except on one occasion, when his physician attempted to turn him on the left side. He then cried out suddenly, "You have killed me!" and placed his hand over the region of the spleen, groaning with pain. He recovered from this attack. The patient died with suppression, though no symptoms of renal disease had been made out during life.

Post-mortem examination revealed a stenosis of the aorta so great that I could hardly pass the first joint of my little finger through it. The surfaces of the cusps were marked by calcareous concretions and vegetations. The heart, and especially the left ventricle, was hypertrophied and dilated. The kidneys presented the usual appearances seen in the large variety of chronic diffuse nephritis, and contained both recent and old infarctions. The lungs also contained infarctions. The spleen, however, and the meninges showed the most important lesions. The first-mentioned organ measured about nine inches in length, and was the seat of numerous infarcts, and of various ages, some of them red, others brown, others yellow, while one had the point of origin for an abscess from which a pint to a pint and a half of dirty grumous offensive matter was discharged.

Emboli were also found in the meshes of the pia, but they had given rise to suppurative and not fibrinous or serous exudates. This acute attack was plainly engrafted on an old one of rheumatic endocarditis.

We have thus seen that a classification of morbid endocardial changes embraces the following varieties:

1. Simple acute endocarditis; 2, chronic endocarditis; 3, acute infective or suppurative endocarditis; 4, tubercular endocarditis; and 5, senile thickening.

And now for an answer to the question that has been proposed by this Section, "Is Ulcerative Endocarditis always a Specific Disease?" I venture to state that ordinary ulcerative endocarditis is merely an ordinary but late phase of acute or chronic endocardial disease, and a very common one—fatal only through its secondary complications, such as cerebral embolism and the like; recovery taking place in a large number of cases, with a more or less damaged brain, kidney, lung, or spleen, as the case may be. In a very limited range of cases—about six per cent. according to my figures—we have the infective or suppurative form, that appears to be uniformly fatal through its septic or quasi-pyæmic characters.

Naturally the diagnosis will not always be made; but it may be inferred with a reasonable amount of certainty where the diagnosis of acute endocarditis is possible, if the secondary involvement of the several viscera I have mentioned is associated with symptoms of a typhoid or pyæmic character in addition to those of simple endocarditis.

The disease appears to attack persons of middle age, lasts from four to six weeks, and the temperature gradually rises until death takes place.

SOME MEDICO-LEGAL CASES.

By HENRY A. RILEY, Esq.,

New York.

The following curious case is found in a recent Illinois court. In an action for an assault and battery, a witness who was a physician was called to testify in behalf of the plaintiff on the trial, and stated that he was called to see the plaintiff professionally after the injury, and described the condition in which he found the patient. The witness was then shown a policeman's "billy," and asked if a blow struck with it on the head or near the temple would or would not be likely to produce upon the person receiving such blow a condition like that in which he found the plaintiff. The witness thereupon, without answering the question, made inquiry of the court whether it did not call solely for a professional opinion, and the court answered that it did. Witness then declined to answer until his professional fee of $10 had been paid or secured to him, and persisting in his refusal the court imposed a fine upon him as for a contempt of court. An appeal having been taken, it was held that the witness having already, and without objection on his part, stated the condition of the patient he had visited, he could not properly refuse to give his opinion as to the cause of the symptoms he discovered to exist, and that the payment of his professional fee could not be made a condition of his answering. The opinion sought was pertinent to the subject about which he had voluntarily testified.

The contest between the undertakers and the Health Board of Newtown, Long Island, where so many of the large cemeteries are located, is likely to be taken into the courts for settlement. The question has certainly two sides, and it is not altogether certain which side will be victorious. It appears that the extent of cemetery property, which is made not taxable by law, is so great that other lands are unduly taxed, and the price of property is depreciated in Newtown.

On the other hand, it is said that the action of the Health Board in fixing a charge of $1 for each burial permit is ostensibly based on the ground that it was a sanitary measure, and that the payment of the money cannot affect the question of health at all. Newtown is certainly not any healthier because all bodies are now interred at a uniform charge of $1, when some weeks since there was no charge at all.

It seems to be clear that the reasons for making the charge will have to be somewhat shifted, as the courts have in a number of cases recently overturned laws said to have been enacted as health measures. A notable instance of this was shown in the Tenement-house Cigar Bill, which forbade the manufacture of cigars in certain classes of tenement-houses. This law pretended to be a health measure, but the Court of Appeals said that it was rather a law to prevent injurious competition in business, and declared it unconstitutional. Some experiences like this may be in store for the Newtown authorities.

The annual report just filed by Dairy Commissioner Josiah K. Brown is an interesting document. He states that the execution of the laws against adulteration has been hindered by some decisions in the courts, particularly that of the Court of Appeals in the Marx case, where it was held that the law prohibiting the manufacture and sale of oleomargarine was unconstitutional. On this

point he says that "the decision has worked to the disadvantage of those who have been anxious to suppress the sale of spurious articles of the character mentioned. Dealers in imitations have in many instances boldly defied even the laws that are beyond question valid. Notwithstanding these objections much has been done to bring offenders to justice. There are now upward of two hundred cases in the courts.

"Many careful tests have been made of the milk supplied to the people of this State, and the results of these tests, [illegible] being, made throughout the State, which fully sustain the correctness of the milk standard established by the act of 1884. Although the sale of imitation butter has been reduced in this State, the sales in the United States as a whole have materially increased since 1883." Dr. R. D. Clark, of Albany, in a paper, included in the report, states that oleomargarine, in his opinion, is dangerous to health, because it is indigestible, is insoluble when made from animal fats, is liable to carry the germs of disease into the human system, and also because the manufacturers, in order to make the compound cheap, insert ingredients which are acknowledged to be detrimental to health.

There have been a number of cases mentioned recently in the daily papers where physicians were charged with indecent assault upon their patients, and it would seem as if there was either a great lowering of professional honor on the part of the physicians, or else a growing desire on the part of patients to take advantage of any opportunities to blackmail their medical advisers.

The latter is, we think, the more likely view, and so serious do many physicians deem the matter that some have adopted the rule not to see female patients except in the presence of a witness. One of the latest cases which has found its way into the courts is that of Dr. Heald, of Leeds, England, who was accused of indecent assault by a young schoolmistress who consulted him in reference to a cough. It was shown on the trial that the patient was subject to attacks of hysteria, and the jury considered the case one of hallucination, or worse, and acquitted Dr. Heald after a short deliberation of only ten minutes.

It will be remembered that about a year since Dr. R. A. Gunn, of this city, charged State Senator Coggeshall with seeking a bribe from him, for favorable action on a bill then before the State Legislature. Mr. Coggeshall denied the statement, but did not avail himself of the invitation extended by Dr. Gunn to sue him for libel. Senator Coggeshall did, however, bring a libel suit against the Rome (N. Y.) *Sentinel*, for publishing the statement of Dr. Gunn, and the proprietors of the paper have filed their answer, alleging that Senator Coggeshall's reputation as a bribe-taker warranted the assumption of the truth of the charge, and alleging further that he was given to intoxication.

HEGAR'S SIGN OF EARLY PREGNANCY.

By EGBERT H. GRANDIN, M.D.,

[illegible]

In the practice of the gynecologist, in particular, it is frequently necessary to be positively assured of the non-existence of pregnancy before instituting such local treatment as the exigencies of the case seem to require. In the absence of such assurance, the sole course open to him is to defer treatment for a variable period of time, until the rational history or repeated vaginal and conjoined examination lead him to think that the case is one where treatment, as far as the interior of the uterus is concerned, is contra-indicated, until the ovum, which he finally concludes is probably contained within this organ, has reached maturity and been expelled. Is there any diagnostic sign by means of which, at the first local examination, the existence of pregnancy may be determined with almost positive certainty as early, even, as the fifth week of utero-gestation? Such a sign is offered to us by H[illegible] and since [illegible] directed to it, fully eighteen months ago, I have had frequent opportunity of putting it to the test, and have, by means of it, been able to assert as early as the fourth to the sixth week that gestation existed. This statement, in face of the teaching of all our text-books that certainty of pregnancy cannot exist until the fœtal heart and fœtal movements are appreciated by the accoucheur, and that before this period all other signs conjoined are simply of presumptive value, undoubtedly appears strong; but my experience, so far as it has gone, justifies me in my belief.

Since my object is to call attention to this sign of Hégar's, and not to rehearse the signs which, in the early months of pregnancy, point to this condition, I proceed at once to its consideration; and, in order to make the sign clear, would call attention to the gross changes which take place in the uterus prior to the second month of uterine gestation: that is to say, before any classical physical signs—such as discoloration of the vaginal mucous membrane, softening of the cervix—have become at all marked. The early rational history I purposely leave out of the question, for such history our patients frequently falsify.

During the first six to eight weeks of pregnancy the changes in the uterus are practically limited to the body of the organ. The uterine body enlarges, especially in its transverse diameter (antero-posteriorly); the muscular substance becomes less dense. These changes are simply the result of the hyperæmic condition into which the corpus is thrown and kept by the engrafting of the impregnated ovum. As the result of such changes, the uterine body loses its nulliparous pear-shape; its contour no longer gradually diminishes as it approaches the uterine neck; the body, on the contrary, bellies out (if I may use the term) over the cervix in all the transverse diameters, in particular, antero-posteriorly, and the organ, instead of being pear-shaped, resembles very much an old-fashioned, fat-bellied jug. These two appearances I have tried to represent schematically below:

[illegible] Not impregnated [illegible] impregnated

The above changes in the consistency and shape of the body of the uterus constitute Hégar's sign, and so far, in at least a dozen cases, it has never failed me in early diagnosis. The obtaining of this sign requires, of course, a certain expertness in the bi-manual palpation, and familiarity with the sensation communicated to the finger by the nulliparous uterus, and the uterus altered pathologically in one or another way. I have found, however, in my clinical teaching, but little difficulty in making even inexpert fingers conscious of the change. In the vast majority of cases, owing to the normally slight anterior curvature of the uterus, the internal examining finger will note this sign to the best advantage in the anterior culde-sac. Here the finger, instead of following the line of the cervix in a gentle curve up on to the body, is at once conscious of the body swelling out to a greater or lesser degree, according to the date of impregnation, over the cervix, and at the same time, bi-manually, the body is faintly boggy, resilient, compressible. If such be the condition of affairs detected by the local examination, in the absence of rational history, in the absence of slight softening at the tip of the cervix (which may, if present, mean erosion), and of mammary signs and blue discoloration of the vagina (both of which, if present, may mean ovarian disease), I now unhesitatingly pronounce the patient pregnant. The question arises, Are there other conditions which may simulate the above sign? There

are two which, I can imagine, might—distended bladder and uterus distended by menstrual blood. Neither of these conditions ought, however, to give rise to error, for a necessary prelude to a careful bi-manual is evacuation of the bladder by means of the catheter; and retained menstrual blood in the uterus, if not accompanied physically by imperforate hymen or vagina, would necessarily be suggested by the history (no ground for falsifying here) before sufficient had collected to give rise to even faint fluctuation. Hyperplasia of the corpus uterus cannot simulate this sign, because in this condition the conjoined touch reveals density; sub-involution cannot, because here the uterus is increased in its longitudinal as well as in its transverse diameters, and conjoined touch, while revealing heaviness and softness, does not reveal resiliency and compressibility. The markedly anteflexed corpus uteri, hyperemic from obstructed circulation, is most likely to simulate Hégar's sign, but in case of such distortion the feeling of resiliency and compressibility is also lacking. In marked retroversion this sign is likely to fail on account of the difficulty of palpating with ease the uterine body. Rectal examination might assist here, but as yet I have had no opportunity to seek for this sign in case of this variety of displacement. Compes (*Berlin Klin. Wochen.*, September 8) ꝛg, ıw ıƨ ' ɥo, as far as I am aware, is the only observer who has published observations in regard to Hégar's sign, says that it may always be obtained to better advantage by means of the thumb in the vagina, the index in the rectum, and the other hand externally. He thus, he tells us, reaches the portio vaginalis with his thumb, places his index finger above the sacro-uterine ligaments, and when the external hand depresses the fundus, is able, to better advantage, to explore the lower uterine segment. I fail to see in what respect this manœuvre is superior to the vagino-abdominal method which I practise, aside from my belief that it must be only very exceptionally that the thumb can reach the cervix *per vaginam* while the index is above the insertion of the posterior uterine ligaments *per rectum*.

Since this paper has already exceeded the limits I had intended, I refrain from quoting more than one case in which I have noted this sign. I report this single case because it emphasizes strongly the value of Hégar's sign in diagnosis.

S——, aged nineteen, was brought to the Polyclinic by her mother in order that amenorrhœa of two months' duration might be accounted for. The girl was sufficiently anæmic to suggest this as a cause, especially as absolutely no rational history could be obtained, either from mother or daughter, which might suggest the physiological cause of amenorrhœa. Examination of the breasts revealed nothing distinctive. In Professor Mundé's absence, I examined the case before the class, and, finding Hégar's sign, pronounced her pregnant. The hymen was intact, the external os at its tip was soft, but this could be accounted for by an erosion resulting from a slight endocervical catarrh. Both mother and daughter were highly indignant, because three days previously a gentleman, whose opinion I should ever rank above my own, had pronounced the girl not pregnant. The assistants were inclined to laugh at my apparent discomfiture, but I clung to my diagnosis, and had the satisfaction of hearing a few weeks afterward that the assistant who had laughed the most had been called from bed, in the small hours of the morning, to remove an eight weeks' ovum from this young girl. As it was a charity case, he was amply paid for his laughter!

Seven of my cases were seen at the Polyclinic in the service of Professor Mundé; four were private, and in these, as well as in the clinic cases, the certainty of diagnosis was established by after-observation. In seven additional cases an early diagnosis was likewise made, but I do not use them in support of my belief in the efficiency of Hégar's sign, because none of these cases were seen a second time. It is in place to state that largely by means of this sign Dr. Mundé was able in one case to make a positive diagnosis as early as the fifth week, although both husband and wife assured him of its impossibility on account of the precautionary measure they were in the habit of taking.

In order to settle the value of this sign positively, it is of course apparent that others must note the result of their experience. As the matter now stands, Hégar believes this sign to be of great value, Compes regards it as positive, and I am inclined, from a limited experience, to consider it infallible.

52 West Thirty-third Street.

Clinical Department.

PAINLESS OPERATION FOR PHIMOSIS.

Dr. W. Rounds Barnes, of Binghamton, N. Y., writes that he performed circumcision upon a man forty-two years of age, after having previously applied a four-per-cent. solution of cocaine for twelve minutes to both surfaces of the prepuce along the proposed line of incision. The patient himself rendered good service in wiping away the blood, and in holding the mucous and cutaneous surfaces together while the sutures were inserted. The hemorrhage was very slight until sensation returned, which was not until the last suture was being put in. The patient remarked at that time that that was the first pain he had felt. The operation occupied thirteen minutes.

THE IMPORTANCE OF ANTISEPSIS IN MIDWIFERY.

Dr. Barton C. Hirst, of 219 South Seventeenth Street, Philadelphia, writes that during his term of service as interne in the University Hospital for Women, in Munich, under Professor Winckel, there occurred a case in the obstetrical wards which strikingly illustrated the importance of a rigid adherence to antiseptic principles in the management of a woman in labor. "The patient was a young primipara, and the labor was progressing favorably, when the interne in charge retired to his room for a few minutes' rest, leaving the case in charge of a student, with directions that he should be called as soon as the os was fully dilated and the child's head began to descend. This was not done, however, and on next entering the ward the interne found that the child had been born, and that the mother was almost exsanguine in consequence of a furious arterial hemorrhage from a torn perineum. The woman's condition demanded immediate action, so the wound was hurriedly tamponed without the usual antiseptic precautions, and the hemorrhage was finally controlled by deep stitches. An attempt was afterward made to disinfect the vagina and the wound with corrosive sublimate solution, but the patient developed all the symptoms of septicæmia, and after an illness of some weeks died. This was the only death from such a cause that had occurred in the hospital for a period of over three months and out of a number of more than three hundred cases."

GUNSHOT WOUND OF THE LIVER.

Dr. A. P. Frick, of Fort Thomas, Ariz. Terr., writes: "W. C. J——, a civilian, who was attacked by Indians at his ranch near Black Rock, Ariz. Terr., was admitted to hospital on November 30th, with three gunshot wounds, caused, apparently, by 44-calibre rifle bullets, which he had received the evening before. He was a large, muscular man, weighing about two hundred pounds, and about forty years of age. One ball had passed through the middle third of the right thigh, in front of the femur, and another had caused a compound comminuted fract-

ure of the lower portion of the left ulna. The third ball had entered the body one inch and a half below the lower end of the sternum, and one-half inch to the left of the median line. The bullet passed slightly downward and back to the right side, making its exit at a point midway between the anterior and posterior median lines of the body, and just under the free border of the ribs. It was at first believed that the liver might have escaped injury. All the wounds were dressed antiseptically, with drainage at the exit of the abdominal wound. On the second day a free discharge of bile came through the drainage tube, and the neighboring tissues were infiltrated with the same secretion. On consultation with my friend Dr. William L. Wardwell, of New York City, who is now visiting at this Post, it was decided that, without interference, the wound would inevitably prove fatal; and that there was but a forlorn hope in an operation upon the gall-bladder, with a view to arresting the flow of bile. This operation was accordingly proposed, but was not consented to by the patient and his friends. Death occurred at 11 P.M. on December 4th, a little over five days from the time of receiving the wounds. No post-mortem was permitted.

POISONING FROM THE EXTERNAL APPLICATION OF ACONITE.

Dr. Herman Gasser, of Platteville, Wis., writes that he was called to see a druggist who was suffering from rheumatism in the feet. The patient had been employing tincture of aconite as an external application, and had used up an ounce in this way in three days. As he was no better, Dr. Gasser ordered the discontinuance of the aconite and gave him salicylate of soda and colchicum internally. On the following morning he was much better and took a hot foot-bath, keeping his feet immersed without rubbing for about half an hour. At the end of this time he began to feel so "very peculiar" that the writer was sent for. He found him sitting in a chair and complaining of tingling sensations, starting from the hands and feet and extending over the entire body, and of nausea. The pulse was weak and slow, and the skin was cool and moist. As he was growing worse and was vomiting frothy mucus, he was put to bed, and hot-water bottles were applied to his body. Although he had taken no aconite internally, the symptoms were unmistakably those of aconite poisoning, and Dr. Gasser was about to give him a hypodermic injection of brandy and digitalis over the heart, when he was taken with a spasm, made a few jerking efforts at respiration, and then seemingly died of syncope. The heart had apparently ceased to beat, and pulsations could be detected neither by the writer nor by Dr. Buck, who was present. Although without hope of restoring the patient, the hypodermic injection was nevertheless given, partly for the reason that it was prepared. In about a minute he began to gasp for air, and the heart could be felt to beat. The injection was then repeated, hot wet cloths were laid over the heart, and an enema of brandy and digitalis was given by the bowel. Reaction was soon fully restored, the pulse and respiration became strong, and the skin warm, red, and covered with perspiration. This was followed by spasms, which were controlled by morphine and ether, and the patient then passed into a restless sleep from which he awoke conscious but dull. The following morning, though feeling rather stupid, he arose and ate breakfast with his family. Dr. Gasser offers the following explanation of the occurrence of poisoning:

"Tincture of aconite is a resinous solution in alcohol, and as fast as it was applied to the skin the alcohol evaporated and the aconite was deposited like a coat of varnish on the skin. (The limbs were bathed with it from the knee down.) The hot-water soaking caused a congestion and softening of the skin, and put it in the best possible condition for absorption."

Progress of Medical Science.

Iridescent Calculi.—At a recent meeting of the London Pathological Society (*The Lancet*, November 21, 1885), Mr. S. G. Shattock read a paper on "Iridescence in Calculi." He showed a group of fifty calculi of most varied form, and having sharp facets. The largest was two centimetres in its greatest measurement, the smallest about the size of a hempseed. A remarkable iridescent, lustrous, yellow color was evident in all. This property was confined to a distinct separable surface layer. The inner substance was phosphatic and composed of conical intersecting tufts of fine acicular crystals. The calculi were removed from the prostate of a man on July 20, 1843. Phosphate of lime and magnesia and ammonio-phosphate of magnesia formed, with carbonate of lime, the chief chemical constituents. A laminated nucleus was found in the centre. Renal and vesical calculi, pseudo-metallic in appearance, had been described in herbivora; these consisted of carbonate of lime. They were very rare in man. The only one he knew of was in University College museum, and was given to the late Mr. Liston by Civiale. Thin sections of the prostatic calculi showed two kinds of structure. The iridescent thin layer was composed of a large number of closely-apposed homogeneous concentric lamellæ, of great tenuity, and translucent. All the calculi examined had a distinct, compact, pale-brown, spherical, laminated nucleus. These were evidently identical with minute prostatic calculi. The porcellanous appearance of certain prostatic calculi was due to a similar disposition of the superficial lamellæ, which, however, were less regularly arranged; phosphate of lime with a small proportion of carbonate formed the bulk of the porcellanous surface. He remarked that all the calculi were made up of phosphate and carbonate of lime combined with a colloidal base. The colloidal base in this case had been found by Dr. Bernays. Mr. Shattock suggested that in all cases in which iridescent calculi were formed the urine contained albumen, though not necessarily albumen from the kidney. In support of this he referred to a case of iridescent calculi shown to the Society last year by Mr. Bilton Pollard, where the calculus was contained in the pelvis, and the urine contained pus. Dr. W. H. Stone had examined the iridescent calculi shown, and had found that the iridesence was a phenomenon of diffraction. In the discussion which followed Dr. Ord said that he did not regard the iridescence as due to diffraction, but to the same class of phenomena as Newton's rings. A typical colloid was the organic basis of such calculi, and the importance of carbonate of lime was great. In the ordinary pearl we had both these elements at work. These calculi must have been formed very slowly.

Spasm of the Sphincter Ani, and its Treatment by Forcible Dilatation.—From his experience in the management of spasm of the sphincter ani, Dr. T. Pridgin Teale (*Medical Times and Gazette*) concludes: (1) That spasm of the sphincter ani, as a cause of constipation, suffering, and ill-health, is often overlooked, and patients are allowed to suffer for years who might be cured in five minutes. (2) That spasm of the sphincter can be arrested by forcible dilatation more satisfactorily, more certainly, more scientifically, and with greater safety, than by division by the knife. (3) That in all operations on the rectum and anus dilatation of the sphincter is an essential, almost an indispensable, element in the treatment.

In Acute Catarrhal Conjunctivitis Dr. Bieloff, of Kiew, recommends the external use of bichloride of mercury in solution not stronger than 1 to 2,000, or gr. j to ℥ iv. of water.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 27, 1886.

THE DOCTOR'S HOBBIES.

IT was, we believe, Sir Walter Scott who said that the architect who knew nothing but architecture was nothing but a carpenter; and Mr. Timothy Holmes, in his address to students, has said that "A man who is nothing but a doctor, is not generally first-rate at that."

It would, perhaps, surprise the profesion sa little, and their patients a good deal, if it were known what hobbies and curious diversions many distinguished and successful physicians have had. If we mistake not, however, it is between art, literature, and horses that physicians who seek some outside interest or means of recreation divide their attention. We have many eminent doctors who are skilled in music or drawing, perhaps good amateur painters or etchers; many are book-collectors or contributors to general literature. Very few, we imagine, take up any collateral branch of science, although we have some excellent botanists and naturalists. The chief drawback to the pursuit of medicine, says Mr. Holmes, "is the labor which it entails, a labor never ending, and which leaves its victim no repose, literally, night or day, and under which men are apt to degenerate into mere business-machines, and to care for nothin gexcept their profession. No doubt, this is a lesser evil than the listlessness which follows on idleness; still, it is an ignoble condition. It deprives a man of all power of companionship with the world at large, and shuts from his eyes many of the sweetest and loveliest things of life. It makes a man the slave of his business, instead of its master, and it confines his mental faculties to a groove, in which they wither, so that business itself soon becomes a dull routine."

The best antidote to all this is the cultivation of a taste for some worthy object. Mr. Holmes, who is himself an excellent Greek scholar, thinks that the best of all tastes is that for literature. To this he adds a recommendation of the cultivation of the art of conversation, an art which has the advantage over reading of being more social and unselfish.

"I believe," says he, "the art of conversation is said to be decaying. The more the pity, for it is a grand art, as well as a most delightful accomplishment, and, to a medical man, who has to associate with all kinds of persons, in all kinds of circumstances, is almost a necessity. But, whatever may be your taste, so that it is innocent and healthy, cultivate it when you are young, and it will help you to resist the pressure of business when you are old. I do not want you to waste your time as students; you have, in fact, not an hour to spare. But healthy recreation wastes no time. No one can study profitably without a large allowance of total rest and change; and in those happy hours it is well to mount your hobby, if only a tricycle, and drive him fearlessly along, forgetting that there is such a thing as anatomy or surgery. You will be none the worse anatomists and surgeons in the long run."

We would gladly second Mr. Holmes' recommendations, but we do so with the feeling that in many parts of this country the struggle for existence is so keen, and the competition so bitter, that the doctor often has not the heart or the opportunity for diversion. It is all medicine or nothing. Besides, it must be admitted that popular feeling is against the doctor who does anything but attend strictly to business. We have even heard of a well-known practitioner who removed all the books, of which he had a large number, from his office, because he found his patients thought that perhaps he studied too much, and was not, therefore, "practical." The man in any calling who has to earn his own living must be a slave, and this is especially true of the doctor. Still, everyone can find a way to prevent his "slavery" from being ignoble or wearisome, and, after all, the physician knows life and enjoys it as much as anyone.

THE GOLDEN RULE IN CONSULTATIONS.

So much has been written regarding the unpleasant side of doctors' consultations that it is a relief to read of the experience which Sir Spencer Wells had, when a very young man, still in his medical pupilage under Mr. Marsden, of Leeds:

"One evening a farmer rode up to Mr. Marsden's, who was the nearest medical man, to beg him to go at once and see a girl who was very ill. Marsden was not at home, so I offered to go. The farmer hesitated, but he was very anxious, so he said, 'Well, lad, get on my horse, and I'll go on for our doctor, Mr. Braithwaite.' So I rode to a small farm-house near Chapeltown, and found a room full of people, and a girl insensible on the bed. I remember having her clothes loosened and opening a window, and, when she began to shiver, trying to make her swallow a little brandy-and-water. Then Braithwaite arrived, and very soon took me into another room, after saying to her mother, 'Give her two teaspoonfuls more of that brandy-and-water;' but as soon as we were alone he said: 'It was very wrong to give her brandy-and-water. It is the first stage of some eruptive fever. But a teaspoonful won't make any difference, and it will show that I did not differ from you. If I had,' he said, with a kind smile, 'perhaps they would not believe either of us.' There was something in this way of treating a junior—so much good feeling mixed up with so much knowledge of human nature—that I have many times since, when consulting with juniors, followed, or tried to follow, Braithwaite's example."

There is no provision in the Code that covers this ground, yet it is an unwritten law for every gentleman who is inclined from purely conscientious motives to

deal fairly with his brother. In this respect he is avoiding even the appearance of evil intent. The consulting physician has, as a rule, every advantage in his favor. The patient looks to him as one eminently qualified to give advice, and the family physician honors him by calling him to help in time of need. The consultant cannot be too careful of his words and acts. His duty is, of course, to help the patient. This is best done by strengthening the confidence of the patient in the family attendant. Nothing is more indiscreet than to cause the patient or his friends to believe that the line of treatment is to be altered as the result of the consultation. When a change in this repect is demanded, it can always be done in a manner that will not reflect on the skill or judgment of the physician in attendance. We speak advisedly when we say that in nine cases out of ten there is no immediate necessity for a radical change. When the latter is agreed upon, no harm is done in allowing it to be understood that the suggestion comes from the family attendant, who may ask the consultant to indorse him.

For instance, here is a case in point. The patient is suffering from great prostration, and the amount of stimulation is apparently not sufficient. The consultant suggests privately to his *confrère* that more alcohol is needed, and perhaps an increase in the dosage of digitalis. The case is urgent, and time is precious. Both physicians appear before the family. The consultant is the spokesman. The patient is seriously ill, so the friends are informed. It has been decided to continue the same line of treatment, in a vain hope, perhaps, of its good result. The diagnosis has been confirmed, and nothing more seems necessary to be said, when the family physician asks the consultant why it would not be proper to try the effect of even increasing the stimulant, and of adding to the number of "the drops." The consultant, of course, thinks it would be well, and it is well for all concerned. The patient gets the benefit of the change, the consultant and family physician conjointly get all the necessary credit, and medicine, in the eyes of the patient, at least, becomes an exact science. In our fight against ignorance and prejudice, it always behooves us to fly a clean flag at our masthead.

THE NEW YORK ACADEMY OF MEDICINE.

Sufficient time has elapsed to show in a measure the results of the policy adopted by the New York Academy of Medicine in organizing into sections, and thus distributing its forces upon more special lines of work.

The question of the propriety and policy of this move, if not quite settled, is at least very nearly so. One or two of the sections only have been thinly attended, and these will probably be abandoned, and the work concentrated on those of which the need and usefulness have been clearly shown.

At all events, it is very apparent already that much good has been accomplished, and that the profession in this city was never more active or harmonious in its scientific work. The Academy is unquestionably doing a great deal for the profession of this city, and is constantly becoming an organization of greater prominence and helpfulness. Being now freed from debt, the possessor of an excellent building, a large working library and reading-room, and an energetic set of officers, there is every reason to predict for it a still more brilliant future.

DEATHS AMONG DOCTORS.

The popular view that doctors are healthy and long-lived (and mainly because they do not take their own medicines) is not borne out by some recent investigations of Dr. William Ogle, Superintendent of the Statistical Department at the office of the Registrar-General of Great Britain. Dr. Ogle finds, first, that the average annual death-rate among medical men is greater than that in any other learned profession, and greater than the average death-rate among males over the age of twenty of all classes, being at the rate of 25.53 per 1,000; secondly, he finds that the death-rate among physicians has steadily increased from the year 1860–61, when it was 23.60 per 1,000, and 1870–71, when it was 24.98 per 1,000. This increase is confined, however, to physicians over the age of forty-five. The mortality under that age is not so great in proportion as formerly.

Regarding the death-rates among doctors as compared with that in other callings, Dr. Ogle's figures show that this rate is 15.93 in the clerical profession, 20.23 in the legal profession, and 19.90 in the scholastic profession, while in the medical profession it is, as has been stated, 25.53. The rate in the medical profession is thus not only higher than in any of the other learned professions, but also compares unfavorably with the rates in most other trades and industries, and is indeed "only exceeded by the rates in certain trades and occupations that are notoriously unhealthy."

An investigation was made as to the diseases of which medical men die, and comparative tables are given showing the deaths per 1,000,000 among doctors and among all other classes respectively. From this table we find that among 1,000,000 doctors 59 die of scarlet fever, while among 1,000,000 of other men over twenty years of age only 16 die annually of this disease. The comparative figures for other diseases are, for doctors and all other classes, respectively, as follows: typhus fever, 79, 38; diphtheria, 59, 14; enteric fever, 311, 238; malarial fever, 46, 11; erysipelas, 172, 136; alcoholism, 178, 130; gout, 291, 78; rheumatic affections, 251, 215; malignant disease, 879, 790; diabetes, 284, 108; diseases of the nervous system, 4,565, 4,268; diseases of the circulatory system, 4,142, 2,934; liver disease, 1,744, 744; other diseases of the digestive system, 973, 632; calculus, 86, 30; diseases of bladder and prostate, 634, 287; other diseases of the urinary system, 1,520, 665; suicide, 363, 238. In regard to phthisis and diseases of the respiratory organs alone do medical men compare favorably with other classes.

On the other hand, they are more subject to all the infective diseases, except small-pox, protection from the last being undoubtedly a tribute to the efficacy of vaccination. The death-rate from accidents is disproportionately high, as is also that from suicide. We are even told that the suicide-rate is increasing. Thus, the annual rate for the six years 1878–83 was, for the clergy, 128; the lawyers, 354; the doctors, 464. Medical men pre-

fer to use poison in committing suicide, and they especially favor prussic acid.

The excessive death-rate from liver diseases is attributed by Dr. Ogle to the neglect by medical men, as a body, of those wise rules of diet which they lay down for the guidance of their patients. The excess of mortality from liver diseases in the medical profession is 134 per cent., and from urinary diseases 128 per cent.; while, on the other hand, the excess from diseases of the organs of circulation is only forty-one per cent., and from diseases of the nervous system only seven per cent., above the rate among the general population. The excess in the death-rates from diabetes and malignant diseases is attributed to the probability that the diseases to which medical men succumb are more correctly diagnosed and more carefully stated in the death-certificates.

The application of the mortality-rate among English medical men to those of this country gives us some interesting figures. Assuming that there are 75,000 active practitioners of medicine in the United States, the annual loss by death would be 1,912. On the other hand, the annual increment by graduations from medical schools alone has in the past three years averaged 4,000 doctors. There is thus an absolute gain of 2,000 doctors to the medical profession of this country annually. Of course, our profession loses by invalidism and changes to other pursuits. But it also gains a large numerical reinforcement from European schools and from irregular practitioners.

MUTUAL PROTECTION AGAINST BLACKMAIL.

In an address recently delivered before the Chicago Medical Society, Dr. E. J. Doering stated that suits for malpractice against physicians were on the increase. To this the cold world might say that it was an evidence that doctors are getting less skilful, or more careless. The testimony of lawyers, however, as well as the records of court decisions, show that such is not the case, but that a very large proportion of the suits in question are based on the flimsiest evidence, and are really only a form of blackmail.

If the profession, therefore, is every year being more and more systematically blackmailed through the inauspicious conjunction of rascally patients and shyster lawyers, the question arises, What can be done to prevent it?

Dr. Doering proposes to form a society for mutual protection against blackmail. "My plan," he says, "is to form an association composed of about two or three hundred members of the regular profession, all of whom shall be of acknowledged ability, possessing a good moral character, and standing well in the community. Said association to employ one of the prominent law firms by the year, to furnish the members such legal advice as they may desire, and defend any suit arising against the members in the discharge of their professional duties. From correspondence with lawyers I find that an annual due of five dollars for a membership of two hundred would suffice to cover the expense. An initiation fee of five dollars would create a sufficient fund for court expenses.

Letters from a number of Chicago physicians, some of whom speak with the deep feeling and large enlightenment of practical malpractice-suit experience, are printed. Out of the twelve gentlemen who write all but two or three are heartily in favor of the project. Legal opinions from two well-known lawyers support also its practicability.

The objections given to the scheme are: that the fact of membership in such an association would prejudice a defendant before a jury; that some physicians might prefer to trust their cases only to counsel of their own selection; and, finally, that a certain small proportion of malpractice suits are justifiable, and an association should not be asked to support and defray the expenses that result from ignorant and careless work.

On the other hand, the existence of such an association would, it is believed, tend to lessen very greatly the attempts at blackmail, and if the objects of the Society were enlarged and made to include the protection of professional secrets and confidences reposed in the physician by his patients, there would not be, according to legal opinion, any bias created in the minds of a jury, through reason of membership in such society.

The general principle involved in Dr. Doering's scheme should have unqualified endorsement. Distasteful as anything like "trade-unionism" is to many, it is a necessity of the day. Says Dr. Asche: "While other professions are laboring, organizing, scheming, for their own advancement and for the establishment of their own power over society, ours has so completely forgotten its common interest in individual sacrifice, that to this day it remains, as has been well described for all practical purposes, a disorganized rabble."

The medical profession must unite for its own protection, and the more it works together in such way the greater harmony and good feeling, as well as material prosperity, will result.

The question of the propriety or need of organizing a special association for mutual protection against blackmail will be answered differently in different localities. In most cases, as in this city, the machinery of the county society can perhaps be used with sufficient effectiveness to accomplish the purpose.

OUR ENLARGED NUMBER.

No better evidence of the activity in medical work can be given than in the present issue of The Record, whose columns are expanded into an enlarged number to give place to the great amount of valuable and fresh material which has crowded upon us. The large circulation of this journal tempts the leading authors throughout the country to send us their best productions, and while we labor under an embarrassment of riches we owe it to our readers to do the best in our power to give as well as receive. Notwithstanding our efforts to condense articles and economize space, our columns have become chronically overcrowded, forcing us not infrequently to decline the publication of papers which, under other circumstances, we should be glad to use if authors would make due allowance for time and opportunity. It may not be known to many of our readers to what extent our method of abstracting the pith of communications has been carried, as shown in the number of short items

which represent in many instances long papers. THE RECORD is already so large that it is difficult for our readers to digest its material in the intervals of its frequent issue, and no pains are spared to compress everything into the smallest possible space. With the best intentions in this direction we are still laboring against heavy odds, and ask authors and readers to be patient accordingly; our only comfort is that we are thus enabled to represent the best medical thought of the day in an attractive and available form.

News of the Week.

THE DOG AND HIS DAY.—Ten thousand dogs have been sacrificed to the hydrophobia scare in London.

A NEW MEDICAL SOCIETY, of a private character, meeting monthly, has been organized in the neighborhood of Yorkville, this city. The officers are: President, Dr. J. L. Morrell; Vice-President, Dr. W. A. Hume, and Secretary, Dr. Alpheus Freeman. It is called the Lenox Medical Society—why, we are not informed.

THE FIRST SUCCESSFUL EXCISION OF AN ENDOCRANIAL TUMOR was recently made by Dr. Durante, of Rome. The patient was a middle-aged woman, with a fusi-cellular sarcoma arising from the dura mater at the base of the left anterior lobe of the brain. The growth caused left exophthalmos, loss of sense of smell on the left side, and mental hebetude. The patient made a good recovery.

THE SIMS MEMORIAL FUND.—The following gentlemen have subscribed to the Sims Memorial Fund since our last published acknowledgment: A. E. Macdonald, M.D., New York City, $5; J. L. Morrell, M.D., New York City, $5; J. W. Howe, M.D., New York City, $25.

THE TREATMENT OF DIPHTHERIA BY THE GALVANO-CAUTERY is pronounced to be wonderfully effective by Dr. Bloebaum, of Coblenz. He has tried it both on animals and man. A single thorough cauterization causes a remarkable change in the character of the diseased surface.

LAPAROTOMY IN COLORADO.—The Denver *Medical Times* reports 34 abdominal sections performed by twelve Denver surgeons, with 18 deaths and 16 recoveries. Denver is still a little behind Birmingham.

THE IDEAL STATE OF THE PROFESSION, says the *Southern California Practitioner*, "would be with every physician a writer—at least, every one in active practice; for every man who takes the responsibility of human life upon his hands should neglect no means of educating himself for the conscientious and successful practice of his high calling, and the habit of thinking upon paper is possibly of all means the most productive in solid results." Our contemporary thus appears to believe that physicians should write as a matter of self-education, and from this point of view the further advice that he write on every-day matters is not bad. "A plain, carefully studied, carefully-reported case of phthisis, or of fracture of one of the large bones, will be of more profit to both writer and reader than an article upon morbus Addisonii or ligature of the common carotid." This may be true, but if every physician should begin to report his cases of phthisis and of fractures, medical literature would be somewhat prosaic and uninstructive, though of unutterable copiousness. There are very few phases of the troubles mentioned which have not been well and repeatedly described. We should say to the physician: Write for your own benefit as you will; the habit of recording cases leads to accuracy in thought and method, and often reveals to the physician unsuspected lapses in his knowledge and observation of the patient. When it comes to publishing, however, it must be borne in mind that cases are only worth presenting to the profession when they are novel and unique, and therefore interesting; when they illustrate some new or clear up some disputed point in the history of disease, or when they throw light upon the treatment.

THE POPULARITY OF COLD COMPRESS IN BERLIN.—The Berlin correspondent of *The Therapeutic Gazette* writes: "Among the therapeutic measures in vogue in Germany there is none which attracts the attention of the American physicians so eminently as the water-compress. It is no fable that the 'compress,' as it is briefly called, is prescribed for every affection of the throat and lungs; for a clinical experience of nearly three months in the Charité and other hospitals convinced your correspondent that it is the first thing ordered in nearly every ailment of the respiratory tract. A piece of linen, being of the size of a napkin if intended for the throat, or of the size of a towel if intended for the lungs, is dipped into cold—not lukewarm—water, applied to the desired locality, and retained *in situ* by means of a woollen shawl or oil-silk, and renewed every half-hour. A poultice is never exhibited for these affections. The compress, as may be expected, has also become the routine treatment in every household, and is quite familiar to every mother and nurse. Your correspondent has taken especial pains in tracing the therapeutic results of this procedure—which, of course, is often accompanied by medicinal treatment—and feels highly gratified with the results observed. The value of this hydriatic procedure consists in the frequent renewals and prolonged application—extending often over two to three days—of a medium which not only abstracts the surplus of heat in the part, and by its secondary physiological action dilates the vessels of the integument, and thus relieves the engorged internal parts, but which also has an undeniable invigorating influence on the nervous system. It seems superfluous to add that strict individualization is, as in all hydriatic procedures, an indispensable requisite in the application of the cold compress. If in a patient the nervous energy is profoundly lowered, the application of cold would naturally only deepen the existing prostration and lessen the resistance against the disease. If, however, we deal simply with a loss of innervation, the usual incumbent of nearly every affection, the application of cold would prove a powerful stimulant to the nerve-centres, and alongside of the above-mentioned local effects of the application, materially fortify the chances of recovery."

THE DEATH OF LUCHSINGER, Professor of Physiology at the University of Zurich, is announced.

DR. W. E. MILBANK, of Albany, is appointed a member of the State Board of Health of New York, to fill the vacancy caused by the death of the late Dr. John Savage Delavan.

A Small Infant.—A Utah physician announces, with considerable pride (in *The Weekly Medical Review*), that his wife has presented him with a full-term female infant, weighing, with handkerchief and shawl, only two pounds and six ounces. The child is plump and healthy. We suspect that the doctor is a homœopath.

The Canadian View of It.—What we maintain is, that many of the sections, as at present organized, are controlled by men who evidently have not the confidence of the scientific workers in the United States, and are unknown abroad. At present, the prospect is that the *peers* of the men who organized the London Congress will be absent from the Washington meeting—the men who, in the United States, occupy positions in the medical world corresponding to those held by Gull, Jenner, Wilks, Erichsen, Paget, Fraser, Flower, and others who made the gathering of 1881 so brilliant. As well may we suppose that the British profession could have made that meeting the success it was without men of this stamp as that the American profession can do without the co-operation of such men as Agnew, Bigelow, Hamilton, Da Costa, Pepper, Mitchell, Loomis, Bowditch, Billings, Dalton, Martin, Leidy, Lusk, Thomas, Barker, Jacobi, Wood, Bartholow, and others who remain irreconcilable. Bombast and bluster will not cover up the disagreeable truth which is quite evident to outsiders, if not to Dr. Brodie, that, unless the present executive of the Congress patch up this unseemly quarrel, the meeting of next year is doomed to failure. The recent attempts to effect a compromise do not appear to have been successful, and we can assure Dr. Brodie that, if matters remain as they are, "the most perfect and elaborate arrangements" will avail but little to attract foreigners in the absence from the sections of such a number of the men who have made American medicine and surgery what it is to-day.—*Canada Medical Journal.*

The Committee on Public Health of the House of Representatives has been abolished. Sanitation is evidently not a Democratic science.

A Fatal Error in Diagnosis.—The principal surgeons of the Hospital St. Spiridon, of Jassy, a city of Moldavia—Drs. Russ, surgeon-in-chief, and Scali, assistant surgeon—lately committed the unpardonable blunder of mistaking a case of seven months' pregnancy for one of cysto-sarcoma of the right broad ligament. An operation was undertaken for the removal of the supposed tumor, when a well-developed fœtus was found of the age before stated, and which lived several hours. The details of this shocking affair are given in the *Gazetta Medicala Jassy*, a journal edited by members of the hospital staff. The mother died on the eighth day after the operation. The surgeons concerned in this case were condemned by the Superior Sanitary Council, with the recommendation to the proper authorities that their licenses be revoked. They, however, appealed to the courts, and, after a hearing, were acquitted.—*Boston Med. and Surg. Journal.*

The Kansas City Medical Index appears in a new crushed-strawberry cover and a generally improved and attractive make-up.

Indiana Medical Practice Act.—The quarterly report of the Illinois State Board of Health says: "An act regulating the practice of medicine, surgery, and obstetrics was passed by the last Legislature of Indiana, the same going into effect on July 23d. While the law is better than none, it is yet very defective in that it leaves the county clerks the judges of the reputable character of medical colleges, thus placing a most important trust in the hands of officials who, however honest they may be, cannot have the special acquirements necessary to judge correctly regarding a medical school's standing; and it is to be feared that this provision of the law will stimulate the graduation of incompetent individuals."

An Alleged Specific for Diphtheria was recently announced by a Mr. Greathead, of Melbourne, Australia. Mr. Greathead revealed the secret of his remedy (which was simply sulphuric acid), and has appealed to the Colonial Legislature, and asked for an investigation of it by a committee of that body.

The Medical Profession in Congress, and in the British Parliament.—The new Congressional Directory gives the names of the physicians who are members of the present House of Representatives. The list comprises Drs. W. H. Cole and F. T. Shaw, of Maryland; Drs. I. M. Evans and L. E. Atkinson, of Pennsylvania; Dr. W. H. Ellsberry, of Ohio; Dr. John Swinburne, of New York; Dr. R. T. Davis, of Massachusetts; Dr. A. M Dockery, of Missouri; and Dr. J. H. Gallinger, of New Hampshire. The Medical Register and Directory of Great Britain gives a list of sixteen medical men now in Parliament. Some of these, says *The Medical Press*, are *recubantes in nominis umbrâ*. It appears that only two of these doctors are Conservatives, while ten are Liberals and four Nationalists.

The Insane and Defective Classes of New York.—The number of insane persons in the charitable institutions of the State, October 1, 1885, was 12,707, being an increase of nearly six hundred over the previous year. The State and other asylums are full, and there is an urgent demand for further accommodations. New York has 4,040 insane persons, and Kings County 1,350. The average number of blind in the State institutions is 373. The deaf and dumb pupils number 1,289; an increase over last year of 38. The number of patients in the hospitals is 3,397. The number of dispensaries is 43; of inmates of poor-houses, 70,501; and of outdoor paupers, 55,500.

The Ohio State Sanitary Association held its third annual meeting at Columbus, on February 24th and 25th. This is a volunteer sanitary organization, which is doing its best to make good the absence of a State board of health. The intelligent legislators of Ohio refuse to see the need of this, although thirty-one sister States now have health boards. Professor Edward Orton is president of the Sanitary Association; Dr. R. Harvey Reed, secretary.

Always Ahead.—American women menstruate earlier and cease to menstruate later than the women of the Old World, according to Dr. James R. Chadwick.

Reviews and Notices.

CUTANEOUS MEMORANDA. By HENRY G. PIFFARD, A.M., M.D., Clinical Professor of Dermatology, University of the City of New York; Consulting Surgeon to the Charity Hospital, and to the Bureau of Out-door Relief, Bellevue Hospital. Third Edition. New York: William Wood & Co. 1885.

THIS book is one of the series of Wood's Pocket Manuals. It is an excellent little work, written in a clear style, and illustrated by a number of well-executed woodcuts. There are many large works on diseases of the skin which contain much less information of practical use to the general practitioner than does this neat little volume.

MANUAL DE TECHNIQUE DES AUTOPSIES. Par MM. BOURNEVILLE et P. BRICON. Paris: A. Delahaye & E. Lecrosnier. 1885.

THIS little book is meant to serve as a guide to students and practitioners in the performance of post-mortem examinations, and it admirably fulfils its purpose. There are a few illustrations, which have the merit, that woodcut representations of anatomical preparations do not always possess, of distinctness.

DIE DIPHTHERITISCHE ALLGEMEIN-ERKRANKUNG UND DEREN BEHANDLUNG. Von DR. ED. SCHOTLIN. Berlin: A. Hirschwald. 1885.

THE author regards diphtheria as of a double character, existing as either a local disease, affecting only the external organs, and perhaps running its course without manifesting any general symptoms, or a general disease with local manifestations. In this monograph the latter form only is under consideration. The notes of a number of cases with local manifestations in various organs, both internal and external, are given in full, and the concluding chapters are devoted to the subjects of prognosis and treatment.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 22, 1886.

DANIEL LEWIS, M.D., PRESIDENT, IN THE CHAIR.

DR. JOHN C. PETERS read a paper on

THE PRESENT AND FUTURE WATER-SUPPLIES OF NEW YORK,

in which he set forth their deficiencies and dangers, by first describing the location and dimensions of the proposed Quaker Bridge Dam, the estimated amount of money which it will cost, and the length of time required for its construction. Further, the project of ponding a series of lakes in the region of the Mahopac, where the water can be stored subject to draught during low water in the summer season.

There is no doubt that the Croton supply is the purest supplied to any city, but before it reaches the city it becomes very much changed by exposure to unsanitary conditions along the course of the river, more especially along the east branch. The promise, however, has been made that this portion shall be thoroughly sewered. By proper protection against sewerage, the water-supply of New York may be the best in the world.

The Committee on Hygiene are unanimously in favor of the Quaker Bridge Dam, because of the immense increased supply which it will afford; and that the ponding of water and allowing it to run over the Croton Dam would not be best, because of the very great loss of water which would at times occur.

Dr. Peters then read from records furnished by the Board of Health, in which the results of special inspections were given, showing that the filth from slaughter-houses, dairy- and horse-stables, privies (1,879 in number), etc., are constantly flowing into the Croton River, in astounding quantity.

The correction of this tremendous evil is within reach of existing laws, and these nuisances should be swept away without delay.

The conclusions of the Committee on Hygiene were, that the Quaker Bridge Dam is unobjectionable from a hygienic standpoint; that the Sodom Dam should be constructed at once to furnish a quick water-supply; that means should be taken to improve the quality of the water; that asystem of sewers should be constructed to receive the sewerage from the Croton water-shed; that a safety strip of land one-fourth of a mile wide, to preserve the purity of the Croton River, should be bought.

DR. L. JOHNSON discussed the paper and directed attention specially to the fact that, in proportion to the shallowness of lakes is the impurity of the water, illustrated by records of dredging Seneca, Cayuga, and other lakes for shells. Vegetable matter is a growth of shallow water and high temperature, and he believed that stagnant water was unhealthy by reason of the presence of low vegetable organisms.

DR. PETERS suggested the appointment of a committee to appeal to the Croton Water Department, the Aqueduct Department, and to the Board of Health. The question was subsequently referred to the Committee on Hygiene, after the adoption of resolutions.

DR. JOSEPH A. ANDREWS then read a paper

ON CONTAGIOUS EYE DISEASES,

the object of which was not so much to propose any opinions which were absolutely new, as to refer to some views which have been already advanced by others, to support them by additional evidence, and apply them to a number of diversified facts in connection with simple catarrh, trachoma, diphtheritic conjunctivitis, and the ophthalmia of the new-born.

The paper was discussed by DR. ROOSA, who said there was no end of children who recovered from contagious eye diseases *while* in the asylums, but by the proposed law the breaking out of epidemics can be prevented, and the general condition of the eyes of all the children can be greatly improved. He does not approve of the use of nitrate of silver in the acute stage of purulent ophthalmia, but relies on cold applications and thorough cleanliness.

DR. DERBY continued the discussion and supplemented reports already made, in which it appeared that fifty per cent. of the inmates were suffering from contagious eye diseases.

DR. O. D. POMEROY referred to the fact that some children will never recover from their chronic eye disease except they are sent out of large institutions, and then they recover spontaneously. He advocated strict quarantine, although it is a difficult question to deal with.

DR. MITTENDORF spoke of the danger which the child carries home when removed from the asylum.

DR. WEBSTER spoke of the possibility of contagion without contact. He had never seen but one case which seemed to illustrate this possibility.

DR. LESZYNSKY referred to the fact that many of the children suffer from leucorrhœa in one public institution, and in a number of instances it seemed evident that the ophthalmia originated in this affection.

DR. WEEKS believed that it had been proved positively that gonorrhœoic ophthalmia is due to a micro-organism, and that what will kill the coccus will cure this ophthalmia.

THE PRESIDENT announced the death of Drs. H. Assenheimer and Alfred C. Post, after which the Society adjourned.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 18, 1886.

A. JACOBI, M.D., PRESIDENT, IN THE CHAIR.

THE Corresponding Secretary, DR. WESLEY M. CARPENTER, reported the death of their highly esteemed and Honorary Fellow,

ALFRED C. POST, M.D., LL.D.,

and the President was empowered to appoint a committee to prepare memorial resolutions.

DR. H. D. CHAPIN then read a paper (see p. 230) on

RHEUMATISM IN EARLY LIFE.

The discussion was opened by DR. JOHN C. PETERS, who agreed, in the main, with the views set forth by the author of the paper. It was the indistinct forms of rheumatism that lay the foundation of other diseases to which he had paid attention more especially, unattended with any acute joint affection; or, at least, the latter was secondary. Pains in the muscles, soreness on moving, stiffness on bending or stooping, etc., were the most common precursors of the more serious manifestations of the disease. Endocarditis could be recognized long before there was pain or palpitation, and so, also, did recovery take place perfectly so far as the general health was concerned; but relapses were common in the course of one or two years, and finally the patients die with cardiac hypertrophy and valvular disease.

He had seen several cases in which chorea and rheumatism were associated. Dr. Peters also believed in rheumatism of the mucous membranes; rheumatic affection of the muscles of the throat, indicated by pain in swallowing and redness; pleurisy and also pneumonia, rheumatic in character; and, with Todd and Murchison, maintained that the lithic acid diathesis was at the bottom of a number of acute catarrhal affections. He also believed that a large number of cases of nephritis were rheumatic in nature. He prefers the potash to the soda salts in its treatment. Tepid alkaline (potash) baths, rubbing the children with finely-powdered chalk in cases of excessive sweating, gave great relief. Of special value was the phosphate of soda, and it was the only soda salt he used. The debility attending rheumatism was best combated with tartrate of iron and potash.

DR. J. LEWIS SMITH gave a *résumé* of 73 cases observed within the last fifteen years. He recognized *two* particular causes of the disease—first, taking cold, and second, scarlet fever. Hereditary predisposition was present more frequently, he thought, than was generally supposed. In 18 of the 73 cases, one or both parents had suffered from rheumatism. The disease occurs rarely under the age of two years; undoubted cases, however, occur as early as *six months* of age. In most cases it is a mild affection when it occurs in children. It usually begins in the joints of the lower extremities and extends upward, attacking corresponding joints on the two sides. It is very seldom so painful as in the adult, and is not attended by so much swelling and redness, and may be regarded as "growing pains."

Under proper treatment the attacks are, as a rule, of short duration, and the pain and swelling disappear within a week. But, however mild the attack, it is a dangerous malady on account of cardiac complications. If the endocardium escapes during the first week, and proper measures are employed, it will not probably become inflamed subsequently.

In 46 of the 73 cases the mitral regurgitant bruit only was present, and when other murmurs were heard, the mitral was the most distinct. Aortic murmurs were present only occasionally. Pericarditis is much more rare than endocarditis; yet it occurs in all the forms of serous inflammation. It is more frequently overlooked than endocarditis by the general practitioner. He had not had any experience in rheumatic meningitis or pleurisy.

Of 68 cases of chorea that had been under his observation, 26 of the patients had had rheumatism, one or more attacks; usually the rheumatism preceded the chorea, but occasionally the chorea occurred as early as the rheumatism. Of the remaining 42, which gave no history of rheumatism, in *eleven* the parents, one or both, had had rheumatism, and in one other case a sister had had rheumatism.

Dr. Smith wished to emphasize the importance of early diagnosis, and the use of appropriate remedies as early as possible. He uses the salicylate of soda, and was inclined to the opinion that it had been given in too small doses. Given in doses of ten or fifteen grains to a child four or five years of age, on the first day, he believed would prevent cardiac complications. But if the case has been going on for a week or more, the remedy does not act as well as when given early in the disease.

He does not accept the theory that lactic acid produced by indigestion is a cause of rheumatism, because in infancy, when lactic acid formation is most abundant, rheumatism is very rare, while in childhood, when lactic acid fermentation does not occur with anything like the frequency with which it does in infancy, the disease is exceedingly frequent.

DR. MALCOLM MCLEAN believed that in every well-marked case of rheumatism occurring in childhood heredity could be determined as the cause of the disease. He also believed that the so-called growing pains were invariably rheumatic. He had noticed one important clinical feature, namely, accelerated action of the heart, continuing for many years after a rheumatic attack, without evidence of cardiac complication.

DR. L. EMMET HOLT believed that as a constitutional affection, which is the basis of a number of disorders, rheumatism is a common affection. The local manifestations, as pain and swelling of the joints, were rare in children. He thought that great emphasis should be laid on the question of heredity, and gave statistics from one of the London hospitals, which showed how large a percentage of the cases illustrated this predisposing cause. He also believed that there was a close connection between quinsy and rheumatism, but had not seen the same in follicular tonsillitis.

DR. S. KETCH spoke of the rheumatoid origin of some of the more chronic joint diseases, and of the differential diagnosis between tubercular and rheumatoid joint affections, with reference to which the literature was very scant.

THE PRESIDENT said that, up to 1880 nearly all the literature on the point mentioned by Dr. Ketch could be found in a book written by Montcarvo, of Buenos Ayres, who refers to an article written by an American, Dr. Mitchell, and published in the *American Journal of the Medical Sciences* in 1831, where, thirty-seven years before Charcot described arthropathies, the same disease was described.

With reference to congenital heart-disease, but few of these patients live very long. Heart-disease, under six or seven years, recurs very frequently, and there are only two causes: first, sepsis (not frequent), and second, rheumatism. If, therefore, disease of the left heart is found in children six, seven, or eight years of age, it must be the result of rheumatism, whether it was diagnosticated or not; and, as a rule, the younger the child the less developed will be the local manifestation of the rheumatic affection.

As to the growing pains, he would criticise Dr. McLean's statement that they are always rheumatic. They are frequently acute rheumatism; but there are two other causes of joint pains in children. First, neuralgic pains about the joints, and not unfrequently complicated with œdematous swelling. When we find painful joints with swelling the diagnosis of acute rheumatism is easily made, but when we find pain on gentle pressure *about*

the joint and the swelling is *about* the joint and not in the joint, it is not to be classed as rheumatism. In the other class of cases, the children that are growing fast have real growing pain. The long bones grow from both epiphyses, and when rapid there is unusual development, which means hyperæmia, and physiological hyperæmia is very apt to turn into inflammation. He did not in these cases refer to the rachitic diathesis at all. When there is such a condition, then the pain is in the epiphyses, and, as a rule, recovery ensues after a time; but sometimes suppuration occurs with diastasis. In such cases of rapid growth the pain is characteristic, lasts for a good length of time, and is real growing pain.

There is another peculiarity about growing pains. Sometimes it is said that children that have been sick with typhoid fever, scarlet fever, etc., have grown very fast while they were in bed. They do grow, and the number of the cases of so-called rheumatism in scarlet fever and typhoid fever, are really cases of growing epiphyses, where the pain is quite local. Not all are such cases, but there are such, and the two conditions have a certain amount of connection with each other.

Dr. J. Lewis Smith said there might be endocarditis without doing sufficient injury to the valves to give rise to a murmur. This would explain the accelerated heart action referred to by Dr. McLean.

The President said that undoubtedly a valvular murmur might disappear within a short time, and remain absent for many years. It might disappear within half a day or in a few days, and because it was not endocardial but simply rheumatic. There is a connection between articular and muscular rheumatism, and not unfrequently what is regarded as endocarditis is nothing more than rheumatism of the heart-muscle which will pass away very quickly sometimes, and afterward endocarditis may develop in these cases, and remain for a long time.

There are cases of endocarditis with murmur, in which the murmur disappears after years, because of cardiac compensation; the heart, however, is not normal, but is enlarged, and the compensatory development is usually best balanced at about the age of puberty in boys, in whom this disappearance of the murmur occurs most frequently.

There are many cases of endocarditis in which there is no valvular disease, but the large majority of cases are known by the valvular affection. There is one kind of endocarditis in which there is no valvular murmur, and that is *ulcerative endocarditis*. If the valves are affected the deposits are not upon the top of the valves, but at their insertion, which explains the absence of the murmur.

Dr. Sell mentioned a case in which, during an attack of rheumatism, decided evidences of endocarditis developed, numerous murmurs; recovery occurred, the murmurs were retained for a long time, the patient also had chorea; but later in life married, became the mother of eight children, and at present there is not the least trace of cardiac disease.

The Academy then adjourned.

SECTION IN PRACTICAL OF MEDICINE.

Stated Meeting, January 19, 1886.

Alfred L. Loomis, M.D., LL.D., Chairman.

Dr. George L. Peabody read a paper (see p. 235) on

THE SIZE OF THE HEART IN CHRONIC DIFFUSE NEPHRITIS.

Dr. A. Jacobi was invited to open the discussion, and said that the exposition which Dr. Peabody had given of his own experience compared very favorably with that given by most Europeans. Not long ago he read a paper by Schatz, in which the writer directed attention to the fact that although general hypertrophy of the heart was very common, he had been surprised at the additional fact that in a large number of cases it was the right heart that was affected, and not the left. It was a peculiar fact, however, in Schatz' cases, that the observations were not very carefully made, because he had omitted every allusion to the condition of the lungs, which probably would have given some explanation of the hypertrophy of the right heart.

Hypertrophy of the heart in nephritis is seen almost exclusively in chronic cases, but there are those which Dr. Peabody, perhaps, has not seen in hospital, but has seen in private practice, in which hypertrophy of the heart is an accompaniment of acute Bright's disease. Thus it appears that it is not necessary for a nephritis to be chronic in character in order to be accompanied by increased weight of the heart. In many of these cases its occurrence is explained in the same way as when found associated with chronic nephritis; that is, a large number are undoubtedly the result of myocarditis, and it is, perhaps, not so much the result of nephritis as it is merely co-ordinate with acute nephritis. Dr. Jacobi believed that in a number of cases, syphilitic, alcoholic, and otherwise, that the condition of the heart and kidney might be explained in the same way; that the heart disease is not the result of nephritis, but that both exist as the result of a general cause.

Dr. Francis Delafield continued the discussion, and said that the question of the condition of the left ventricle of the heart with chronic Bright's disease seemed to him to be an important matter, not only in itself, but on account of the bearing it had on the question of the condition of the vascular system in cases of chronic Bright's disease. So far as figures went, his experience was a good deal like that given by Dr. Peabody, that while hypertrophy of the left ventricle is found in some cases of chronic Bright's disease, it is not by any means a constant accompaniment. The only figures which he had represented the autopsies in cases of chronic Bright's disease which he made between 1866 and 1876. Of these there were 234 of which he was able to give a fair clinical history, and in all of them the kidneys and heart were examined, and in only 34 was there well-marked hypertrophy of the left ventricle. Of these 34 cases the atrophied kidney was present in 25, and the large white kidney in 9.

On the other hand, the number of cases was large in which valvular lesions of the heart, representing endocarditis, were associated with chronic Bright's disease. There were eighty-nine cases in which chronic endocarditis accompanied chronic diffuse nephritis.

There is always a certain amount of difficulty in comparing the experience of different places and countries. Although we have diseases which bear the same name, and which resemble each other closely, yet climate, race, and social conditions certainly make a great difference in the way in which these diseases present themselves to us. So far, however, as we can judge, hypertrophy of the left ventricle with chronic Bright's disease is not so common in New York as it is in some other places.

It had always seemed to him that in connection with the question of the relation between hypertrophy of the left ventricle and chronic Bright's disease, it was always necessary to take into consideration the condition of the arteries throughout the body. It had seemed to him doubtful, indeed, when hypertrophy was present, that it should be looked upon as the direct result of the kidney lesion, but rather that it is the result of conditions complicating the kidney affection, conditions of the arteries which may occur with or without kidney disease; and also that the kidney disease may occur without these changes affecting the arteries.

The morbid conditions of the arteries seemed to be of twofold character, and it was a matter of doubt as to which was the most important. One is the actual structural disease of the walls of the arteries, practically a chronic endarteritis, whether we call it that or call it

arterio-capillary fibrosis, or anything else. The second disturbance is the contraction of the walls of the smaller arteries, and perhaps of the capillaries, occurring from time to time for shorter or longer periods.

These two morbid conditions may occur separately or together. When they are associated the best possible conditions exist for the production of hypertrophy of the left ventricle, and the association of these two conditions is frequently found with chronic Bright's disease; it had seemed to him to be the explanation of the hypertrophy of the left ventricle when it does occur.

For that reason he could suppose that the difference between our experience and that of observers in other countries was not a difference in the character of the nephritis, as probably the kidney affection was the same, but that it was because there was a difference in the frequency with which the chronic endarteritis and the spasmodic contraction of the small arteries was associated with the nephritis. These conditions of the vascular system, although not unknown to us, do not seem to be as common here as in some other countries.

Dr. Beverley Robinson presented a tabular statement of the cases of chronic Bright's disease in which autopsies had been made at St. Luke's Hospital, Dr. Satterthwaite and Dr. Ferguson, curators. The table had been prepared by Dr. Tiemann, house physician, and was an abstract of necropsies, in which lesions indicative of chronic nephritis were observed with special reference to the size of the heart. In 63 of the cases the heart was enlarged; in 5 of these there was cirrhosis of the liver; in 2, aneurism of the aorta; in 16 there was distinct valvular incompetency; in 24, pulmonary disease, in 17 of which it was secondary, and in 7 primary.

In 11 cases the size of the heart was normal; in 2 of these there was cirrhosis of the liver; and in 3 pulmonary disease, 1 secondary and 2 primary. In 7 cases the heart was small; in 1 of these there was cirrhosis of the liver; in 1 aneurism of the aorta; and in 3 pulmonary disease, 2 secondary and 1 primary.

In 81 cases, therefore, of chronic Bright's disease, in the cases usually described as chronic diffuse nephritis, about three-fourths showed decided enlargement of the heart. In more than one-eighth of the cases the heart was normal, and in more than one-eleventh the heart was diminished in size. In the 63 cases of enlarged heart, 16 were affected with valvular incompetency (primary or secondary, was not determined), 5 with cirrhosis of the liver, and 7 with pulmonary affections, which were presumably primary or concomitant. It was fair to assume that three-fourths of the 63 cases of enlargement of the heart were connected solely with, or dependent on, or resulting from, the chronic renal disease. This would make about forty-five cases in all out of eighty-one cases referred to and in which the post-mortem examination of the heart was recorded, or somewhat more than one-half of the total number, where the enlargement of the heart was certainly more or less occasioned by previous or concomitant chronic kidney disease. Of course, in this analysis, all determining influences with reference to enlargement of the heart proceeding from occupation, habit, mode of life, blood condition, general disease, and nervous affections, etc., were not at all estimated. In more than one-sixth of the total number of cases the heart was normal or reduced in size, and despite the complications of cirrhosis of the liver and pulmonary disease, either primary, concomitant, or doubtful.

Dr. Wesley M. Carpenter alluded to the peculiar pathological fact of the absence of cardiac hypertrophy with amyloid kidney, and yet the amyloid kidney rarely, if ever, occurs independently of chronic diffuse nephritis, the morbid condition which at one time was believed to bear the relation of cause to hypertrophy of the left heart.

With regard to the factors to be taken into consideration in determining the existence of cardiac hypertrophy, Dr. Peabody had mentioned, with others, the size and general development of the body. On this point it might be interesting to refer to observations made by Dr. Alonzo Clark, who reached the conclusion that the size of the heart was not materially affected by the size of the adult, unless the distance between the tips of the shoulders was greater than the average.

The influence of occupation on the size of the heart, also, should not be lost sight of, as it was generally conceded by those skilled in physical diagnosis that in male adults who have followed physically laborious pursuits the area of cardiac dulness is almost invariably increased.

When all the sources of error are considered in estimating the existence of cardiac hypertrophy in cases of chronic diffuse nephritis, the conditions at once become so complicated that the observer is very liable to look toward the arterio-capillary system referred to by Dr. Delafield, or to some other general condition, for their explanation.

The Chairman said he had had the impression for a long time that Dr. Bright struck the key-note in this entire matter. Bright, in his earlier paper, directed attention to the fact that there was enlargement of the heart in a large proportion of cases of chronic renal disease, and made the statement that he believed it to be due to the condition of the blood, which either influenced the heart, causing an irritable action, or so acted upon the capillary vessels, or at least the smaller arterial branches, that greater force was required to drive the blood through the minute ramifications of the arterial system.

It seemed to him that the question of hypertrophy of the heart in Bright's disease could not be decided by post-mortem results, that if decided by anything it must be by the character of the pulse; it was a question altogether of arterial pressure. It was very well known that in a certain percentage of cases of chronic Bright's disease there is a continuous morbid arterial pressure, and that in all cases of acute Bright's disease there is temporary high arterial tension; that a patient with acute Bright's disease at the time when he is on the verge of a convulsion gives evidence of arterial tension, and after the disease has progressed a little this arterial tension is no longer present, because there are rapid blood changes, consisting of a deficiency in the nutritive condition of the blood, associated with great disturbance of the vasomotor system; that the heart has no longer, in its degenerated, debilitated condition, power to give high arterial pressure. Under these circumstances dilatation is liable to occur, affecting both ventricles, and when post-mortem examination is made it is difficult to determine whether it does or does not exist, unless more careful examinations are made than have yet been reported with regard to the condition of the heart in these cases. It is the degeneration which takes place that allows of rapid dilatation and great loss of muscular power in these acute cases. It was well known that frequently within a few weeks, in cases of scarlatinal nephritis, evidences of extensive cardiac dilatation were found, and dropsy developed, which sometimes depended on the condition of the heart and not upon the condition of the kidneys.

It seemed to him that we must break away from the old idea that in the kidneys were to be found changes which would explain all those conditions which were grouped under the term uræmia; that there was, strictly speaking, no such thing as uræmia; but that this change in the nutritive quality of the blood produced changes in the arterioles, and in all of the organs, and Bright's disease became a general disease; and that wherever we met with this condition there was a diseased process going on, affecting the vascular tissues of the body, and hence necessarily the glandular.

The statistics presented by Dr. Peabody would seem to point in this direction, for there was no hypertrophy of the heart in a certain proportion of the cases, and

probably because there was no condition of the general system to give rise to it.

Dr. Peabody, in closing the discussion, said that the association of amyloid degeneration of the kidney with chronic diffuse nephritis and the absence of cardiac hypertrophy was perhaps susceptible of an explanation. Undoubtedly the cause of the hypertrophy of the heart was an increased arterial tension, although it was not the purpose of his paper to enter into a discussion of the causes of cardiac hypertrophy. One evidence, however, that such was the fact was that long before we get the clinical evidence of hypertrophy of the heart the evidence of increased arterial tension could be easily obtained, and after it had existed for a considerable length of time, then there was evidence of cardiac hypertrophy. But in those forms of chronic Bright's disease in which the arterial tension was lowered by general œdema, such as usually shows itself with well-marked amyloid disease, the tension necessarily relaxes, and perhaps cardiac hypertrophy might disappear. Possibly this might explain the peculiar association of these conditions.

Without attempting to discuss the cause of cardiac hypertrophy, he simply wished to lay before the Section certain factors which showed that it was less common with chronic diffuse nephritis than was usually supposed, and that the common clinical teaching that the presence or absence of hypertrophy of the left ventricle would enable the observer to diagnosticate the presence or absence of chronic Bright's disease was mischievous, as it had no substantial basis upon which to rest.

He agreed with the Chairman that we could with propriety go back to the so-called chemical theory advanced by Dr. Bright, because it had been abundantly demonstrated that it was impossible by partial arrest of the arterial blood in the kidneys to produce hypertrophy of the left ventricle, for the reason that it had been distinctly proved that by ligating both renal arteries the arterial tension was not raised for any considerable length of time; it is temporarily elevated, but it immediately relaxes, and is not sufficiently prolonged in any kidney disease to produce hypertrophy of the left ventricle.

The topic for general discussion was the question:

ARE THE ANTIPYRETIC MEASURES AT PRESENT EMPLOYED IN ACUTE DISEASE USEFUL AND SAFE?

The discussion was opened by Dr. A. A. Smith (see p. 237).

Dr. A. B. Ball continued the discussion, and said that he should take it for granted that the reduction of temperature was desirable in very many cases, and, if means could be used to effect this end safely, that it would be useful. He then gave statistics, derived from Bellevue Hospital and St. Luke's Hospital, with reference to the use of antipyrin, where it had been administered in doses varying from fifteen to twenty grains, and repeated at proper intervals until the maximum quantity of ninety grains had been administered, in the treatment of typhoid fever particularly. The unfavorable effects of this remedy in the way of nausea and vomiting, as reported by some observers abroad, and also by some in this country, he thought had been due to the use of larger doses of the drug than was necessary. His conviction was that only small doses were required, and, besides, that it was not necessary to reduce the temperature to the normal, but to between 101° F. and 102° F. was sufficient, as in most instances it would continue to fall after this point had been reached. It could be administered by the mouth, by the rectum, or hypodermically. It was generally given by the mouth. When administered hypodermically it might excite considerable inflammatory action, and even abscesses, although the latter occurrence was rare. One advantage of the hypodermic use was the rapidity of its action. Sweating is usually produced; the temperature may fall without the appearance of perspiration. Sometimes the sweating is exceedingly profuse. The effect upon the pulse is not marked. The effect upon the tongue had been remarkable, changing it from the dry to the moist.

The most common drawback to the administration of antipyrin was the production of nausea and vomiting, which appeared in seven out of the twenty cases in Bellevue Hospital, and in two out of the fourteen in St. Luke's Hospital. In none of these cases, however, was it a serious matter. Chills occurred in St. Luke's Hospital in three cases, but in neither instance were they of a serious character. Collapse had not occurred in any of his cases, as had been noted by some observers, and perhaps it had been warded off by the administration of a small quantity of whiskey with the antipyrin.

An eruption had appeared which resembled very much the appearance of measles. A great variety of eruptions had been reported, and it might even become actually petechial. There was no evidence that it exerted any detrimental influence on the course of the fever.

He had always been very skeptical with reference to the use of antipyretics. His own experience in the use of the cold bath had never been entirely satisfactory. But with regard to the use of antipyrin, he had been abundantly satisfied that the patients went through their sickness with less disturbance, with less delirium, and with more quiet sleep than they would have done without the use of the drug.

His experience in the use of kairin had been unfavorable, and he had abandoned it.

Dr. Kinnicutt said that, in discussing the antipyretic powers of the so-called aromatic group (derivatives of benzol), two important points suggested themselves for consideration.

Whether the members of this group possessed certain essentials of true antipyretics, viz., the power to restrain or diminish increased tissue metamorphosis or organic combustion; secondly, whether their use was unattended with injurious effects upon the economy.

We were now in possession of a considerable number of careful observations, which seemed to demonstrate that during the use of kairin, thallin, hydrochinon, antipyrin, and other members of this group, the excretion of carbonic acid and urea was markedly diminished; in other words, that a certain control was exercised by these drugs over increased tissue metamorphosis. The exact method of this action had not yet been demonstrated. From experiments on animals with kairin it had been suggested that, being an easily oxydizable body, it withdrew oxygen from the hæmoglobin, transforming it into methæmoglobin, thereby lowering the oxidation in the tissues. On the other hand, antipyrin had seemingly little effect upon the hæmoglobin.

Although the members of this group, in all probability, possessed little power of controlling specific disease processes, nevertheless it was an interesting fact that the group furnished a large number of our most powerful antiseptics. In attempting to determine the second point, we must rely partly upon such experimental investigations as have been made on animals up to the present time, and partly upon clinical experience.

Morokhovez, of Moscow, had investigated the action of kairin on dogs. In large doses of one gramme injected into the saphenous vein or duodenum, the arterial blood became dark brown; spectroscopic examination showed the presence of methæmoglobin.

Intense dyspnœa followed, with marked lowering of arterial tension, and weakness of the pulse. These effects would lead us to use this drug with great caution in cases of pulmonary affection, heart disease, and anæmia. Clinical experience also, it seemed to him, should lead us to discard this agent in our therapeutics. In his own experience, rigors and chills, depression, and oftentimes partial collapse, followed its use. The same objections did not apply to thallin. The short duration of its effects, however, made it a less desirable antipyretic agent than antipyrin.

He had largely made use of hydrochinon and antipy-

rin, both in hospital and private practice. They appeared to act by dilating the cutaneous vessels, by increasing loss of heat, by diminishing organic combustion. Intra-arterial pressure was not appreciably modified by them, the frequency of the pulse diminished proportionally with the fall in temperature, the respiration was slightly, if at all, affected. Their utility in the treatment of continuously high temperatures, particularly in the specific fevers, must be recognized and greatly appreciated, he thought, by all who had had much experience in their use. He had rarely observed gastric disturbance, and never collapse, produced by either hydrochinon or antipyrin. That a certain amount of temporary depression might be caused by an incautious use of them, he was disposed to admit; at the same time, he believed it could always be successfully combated. The striking improvement in the general condition of the patient during their use, their control of many of the grave symptoms incident to high temperatures, gave them a place, it seemed to him, among the most important therapeutic discoveries of the present time.

In conclusion, he would add a word in regard to the proper doses of hydrochinon, as it was a drug little known in this country.

In a paper published by him last May he had stated his experience on this point. He would read the following extract from the paper referred to:

"Fifteen and twenty grains were the standard single doses adopted. A marked reduction of the temperature was obtained, *without exception*, in all the cases after each administration of the above dose. By repeated observations it was ascertained that after a single dose the temperature begins to fall, as a rule, within fifteen minutes. The minimum level is reached in two to two and a half hours; the temperature then again gradually rises, during another hour to two hours, to its former height. The degree of reduction was observed to vary somewhat, being dependent, apparently, rather upon individual idiosyncrasies than upon the nature of the disease. The minimum fall obtained was 1.5° F., the maximum 5.2° F. In cases where there was a tendency to a continuously high temperature, three or four single doses were given in the course of twenty-four hours, with the effect of maintaining the temperature at a moderate level."

Dr. R. C. M. Page said that he had but little to add to the discussion on the subject of antipyretics in the treatment of acute diseases. During the month of June, 1882, he visited the General Hospital (Krankenhaus, 2,000 beds) in Hamburg, Germany, with special reference to the fever wards. He was informed that they had abandoned quinine as an antipyretic in the treatment of typhoid fever, since it did no good, but, on the contrary, aggravated cerebral symptoms. Antipyrin and the like had not then become known. The water-bath was inconvenient, and treatment by means of the wet pack was tedious. But typhoid fever patients were simply placed on water-beds, each of which communicated at one end (head) with two tubes provided with stop-cocks, one for hot and the other for cold water. At the other end (foot) of the bed was a drain-tube with a stop-cock for letting off the water. A thermometer was attached to each bed so that the temperature could be regulated with precision to any degree required, by simply turning on hot or cold water, as the case might be. On such beds, also, the chances of acquiring bed-sores were reduced to a minimum. Death in the hospital from typhoid fever was exceptional, and then it occurred chiefly among those who, unfortunately, were brought there late in the course of the disease, and were suffering from previous want of care and attention.

Dr. Peabody said, with reference to the production of abscess by the hypodermic injection of antipyrin, that he would like to ascertain how frequently this complication had occurred, as he had used it a great deal hypodermically, and in no case had it produced an abscess. It had seemed to him that the best way to produce the most lasting effect of antipyrin was by the administration of a drachm by the rectum, the effect produced being as lasting as that usually secured by three doses given at regular intervals of one hour by the mouth. He had also failed to notice any evidence of weakening of the heart's action from the administration of this drug, although he was aware that it might be expected to occur from physiological reasons. He had administered it to an infant, ten months old, in doses of three grains at frequent intervals, without producing any depression of the pulse, and always with a happy effect. The child was suffering from broncho-pneumonia, complicating whooping-cough.

Its use in sunstroke had been alluded to, and it was his practice during the last summer to arm the ambulance surgeon of the New York Hospital with a solution of antipyrin, and direct him to at once administer to the patient suffering from sunstroke a hypodermic injection, and then to bring him to the hospital, where he could receive more active antipyretic treatment. In several instances patients had recovered after an unusually high temperature had been reached; in one as high as 111° F.

Dr. L. Emmet Holt referred to the administration of antipyrin in thirty cases occurring in quite young children, and he had yet to see any bad effects from its use He had always been satisfied with small doses. To children under one year of age he had administered two grains for three doses inside of an hour, and then stopped. To children from three to five years of age he had administered from three to five grains every half-hour until three doses had been given. The quieting effect on the nervous system in children had been very striking; so much so, that when a child's temperature was above 104° F., accompanied by an irritability which it had been impossible to quiet, even by the use of opium, two or three doses of antipyrin had succeeded in bringing down the temperature and relieving the other symptoms in a striking degree. With regard to the disturbance of the stomach, he thought it was exceptionally rare. Sweating in children after the administration of antipyrin was not a common symptom. The doses which he had mentioned had been sufficiently large to accomplish the particular object for which the drug was administered, and in the course of an hour the temperature had usually fallen one or two degrees, and subsequently two or three degrees lower. The cases in which he had used it had been typhoid fever, scarlet fever, dysentery, and cholera infantum.

Dr. Putnam-Jacobi referred to one observation which she had made, namely, the administration of fifteen grains of antipyrine to an adult suffering from typhoid fever, of not a very severe type, but which was followed by a sudden fall of temperature from 105° to 99° F. in the course of one hour, and then rising almost immediately. This sudden transit was not at all agreeable, and she had wondered whether it was very exceptional. Great range in the fall of the temperature seemed not to have been mentioned by any of the speakers. Dr. Ball had mentioned the fact that if the temperature fell one, two, or three degrees it might be taken for granted that such lowering was sufficient, but Dr. Putnam-Jacobi thought it might be well to emphasize the fact that when such a lowering of temperature had been secured we were doing all that was safe. She then referred to a case which occurred in Brooklyn, and which she had already reported in a paper read before the State Medical Society, in which the temperature was 106° F. and the child was kept in a bath until the temperature fell to 100° F. and then removed; but the temperature went on falling, and the case terminated fatally.

She would make an additional suggestion—that is, whether the value of an interruption in the course of the fever did not owe its fundamental value to some interruption in the life process which was being sustained in the infectious agent. A small degree of variation in the

temperature will greatly affect all micro-organisms, and perhaps might seriously interfere with the development of all micro-organisms which belong to the pathogenic group, a benefit which the patient would receive apart from that which we get from the direct effect produced upon the heat by the administration of the drug.

The Section then adjourned.

Stated Meeting, January 19, 1886.

ALFRED C. LOOMIS, M.D., LL.D., CHAIRMAN.

DR. F. P. KINNICUTT read a paper on

THE USE OF NITRO-GLYCERINE IN THE BRIGHT'S DISEASE OF NEPHRITIS,

in which he gave a number of interesting cases to illustrate the influence of this drug in reducing albumen. The general conclusion was that the remedy properly administered, was beneficial in the class of cases under discussion.

The discussion was opened by DR. W. H. DRAPER, who said that ever since his attention was called to the value of nitro-glycerine in angina pectoris, by the publication of Murrell's thesis, and subsequently to its utility in uræmic headache and asthma, he had had many opportunities of confirming its efficiency in relieving those symptoms.

The coincidence of the reduction of the arterial tension, which usually accompanies uræmic headache and asthma, with the relief of those symptoms which follow the administration of nitro-glycerine, is strongly suggestive of the explanation commonly given of its action, namely, that it relieves cerebral and pulmonary anæmia by relaxing spasm of the arterioles and flushing the capillaries.

The analogous action of amyl nitrite in preventing epileptic seizures seems to confirm this theory of its effects in the treatment of the uræmic accidents in which it has been most successfully used. There could be no question, judging from his own experience, of the very prompt and decided relief which nitro-glycerine affords to these distressing symptoms, and though it sometimes fails where opium succeeds, it is certainly for many reasons to be preferred to opium, where it gives relief. From his observation the cases in which it failed were those of advanced disease, in which the functional power of the kidney was well-nigh exhausted and the action of the heart was greatly enfeebled.

Concerning the principal point of Dr. Kinnicutt's paper, the utility of nitro-glycerine in controlling the progress of intrastitial nephritis, he had no experience to offer. Dr. Kinnicutt's investigations certainly seem to lend support to the view of Professor Rossbach, that the lowering of high blood-pressure rather increases than diminishes the urinary secretion. As to the effect of nitro-glycerine in diminishing the daily loss of albumen, it seemed to him that a larger number of observations were necessary to establish the uniformity of this effect.

In some observations which he made during his late service at the New York Hospital—less carefully made than those of Dr. Kinnicutt—the results were negative, the excretion of albumen varying from day to day while nitro-glycerine was administered, just as it did when it was withheld.

There was one effect of nitro-glycerine to which Dr. Kinnicutt alluded in speaking of the physiological effects of the drug, but to which, if he remembered rightly, he did not give much prominence from a therapeutical point of view, that is, its effect as a cardiac stimulant.

In the July number of the *Therapeutic Gazette*, Dr. Joseph B. Burroughs, of Manchester, N. Y., published an article recommending the employment of nitro-glycerine as a substitute for alcohol. He asserts that from an extensive experience he has found it of great value in the shock resulting from accidents, in the nausea and faintness following surgical operations, in the failure of the heart's action due to the administration of chloroform, in opium-poisoning, and in the collapse of typhoid fever.

Dr. Draper had used it as a cardiac stimulant with varying results, and was not prepared to say that it had the advantage claimed for it by Dr. Burroughs over alcohol, opium, or digitalis. In one case of shock from cerebral hemorrhage, in a young woman, after confinement, when death seemed imminent for some days from heart failure, he found it of the greatest service. Its effects were most carefully and intelligently observed, and there was no doubt as to its prompt and pronounced effect in regulating and strengthening the heart's action.

Dr. Kinnicutt states his conclusions in regard to nitro-glycerine with a caution as regards its utility in the treatment of nephritis, which is clearly demanded by the present limitations of our knowledge. Of its efficiency in relieving some of the most distressing symptoms which occur in the course of renal disease, he has brought some very conclusive evidence in the cases which he has related.

DR. C. L. DANA said that he had used nitro-glycerine chiefly in nervous diseases, but of late collected some observations on its efficacy in chronic nephritis and on its action as a diuretic. His cases were eleven in number, five of healthy persons, six of cases of nephritis—the five persons with healthy kidneys had had their urine for twenty-four hours measured. They were then put upon doses of one per cent. solution of nitro-glycerine in doses ranging from gt. j. every hour to gt. j. every two hours. The effects were, with one exception, to increase the amount of urine as follows, the first figure representing the daily urine without medication: Case I., urine 36 to 60 to 46 ounces; Case II., urine 72 to 81 ounces; Case III., urine 38 to 46 ounces; Case IV., urine 20 to 28 to 46 ounces; Case V., urine 62 to 72 ounces.

In the six cases of chronic or subacute nephritis the record was as follows:

CASE I.—Acute nephritis, supervening upon a chronic interstitial nephritis. Patient brought in in uræmic convulsions; urine, 1.025, smoky; albumen eighty per cent.; hyaline, fatty, and granular casts; blood-cells. Patient under treatment twenty-one days.

Nitro-glycerine ♏ ij. to ♏ iij. of one per cent. sol. q. 2 h. for three days, then stopped for three days, then given again in doses ♏ j. q. 3 h. to ♏ iij. q. h. for three days, when urine was found to be 1.008, pale; considerable albumen; blood, hyalin casts.

The nitro-glycerine on first trial did not affect the urine. Three days later, when tried again, it caused, in same doses, rapid increase in the amount of urine, up to 100 to 110 ounces daily. After it was stopped the polyuria continued to increase up to 140 to 150 ounces daily. It then gradually decreased. The nitro-glycerine did not clear the urine of blood or of albumen or casts.

CASE II.—Man, aged fifty-five; chronic interstitial nephritis; anasarca; urine light-colored, 1.011; trace of albumen; fatty and waxy casts. Placed on dry digitalis and pot. acet. for three days, then on nitro-glycerine, ♏ ij. q. 3 h. to q. 4 h. for nine days.

The nitro-glycerine caused an increase in the daily urine to over double the original amount (30 ounces to 62 and 80 ounces). The digitalis and potass. given for three days did not increase it. After discontinuance of nitro-glycerine the urine increased in amount for two days, then slowly fell. Patient discharged improved.

CASE III.—Febrile albuminuria. Patient male, aged forty-five; admitted convalescent, probably from typhoid; urine, straw colored, acid; 1.015; albumen, granular and hyaline casts.

For five days patient placed on digitalis and potass. acet., then medicine stopped. In two days renewed again for two days, then stopped, and patient was placed on nitro-glycerine for eleven days, in doses of ♏ j. q. 3 h. to ♏ j. q. 4 h. The urine under digitalis increased slightly. Under nitro-glycerine it did not increase, in fact had no perceptible effect. Patient discharged with only a trace of albumen in urine, but some fatty and hyaline casts.

Case IV.—Chronic nephritis, dating back three years; great anasarca dating back one week; urine smoky, acid, 1.014; albumen, hyaline; granular and epithelial casts.

Placed on nitro-glycerine ♏ j. q. 1 h. to ♏ iv. q. 1 h. for ten days, medicine stopped for ten days and patient put on dry diet. At end of ten days nitro-glycerine renewed, ♏ ij. q. 1 h. to q. 2 h., for four days.

In this case of acute nephritis supervening on a chronic disease, the nitro-glycerine when first given apparently caused the urine to increase in daily amount from 12 ounces to 40 and 50 ounces in two days. After this there was no increase in urine, and no diminution in œdema. Ten days later, while on a dry diet, the drug was renewed, and the urine increased rapidly from about forty to seventy ounces daily.

Case V.—*Chronic nephritis, cirrhotic kidneys, chronic bronchitis, emphysema.*—Woman, aged fifty-six; urine amber, 1.018, acid; trace of albumen; epithelial, hyaline, and granular casts; red blood-cells. Put upon nitro-glycerine ♏ j. q. 5 h. to ♏ iij. q. 2 h. for four days. Medicine stopped for two days, then renewed, ♏ j. q. 3 h. to ♏ ij. q. h., then medicine stopped two weeks. Here the drug increased the daily flow quickly from 32 ounces to 71 and 100 ounces. On stopping the medicine the urine continued to increase for next two days to 112 ounces. The medicine being renewed it fell to 75 and 70 ounces. Then, on stopping the medicine permanently, the flow increased to 133 ounces, kept high for a week, then gradually fell to 43 ounces. Patient improved.

Case VI.—Male, aged forty-four. Patient gave a history of uræmia and dropsy occurring a year ago, and recurring just before admission. No fever. On admission gave symptoms of uræmic poisoning, and had œdema of extremities. No cardiac symptoms, urine negative as to albumen and casts, 1.029, alkaline.

Placed upon nitro-glycerine ♏ j. t.i.d. to ♏ ij. q. 2 h. and kept up for nine days. Urine increased from 25 ounces to 45 and 50.

From his experience Dr. Dana concluded that nitro-glycerine was a powerful and rapidly acting diuretic, both in health and in certain forms of chronic nephritis; that it must be given, however, in frequently repeated doses of ♏ j. to ♏ ij. every two hours; that in acute renal congestion or inflammation it apparently did not act so well; that it did not appear to clear the urine of blood or greatly lessen the percentage of albumen; that in some persons it does not seem to have the diuretic effect very markedly, and that, after stopping the drug, the flow of urine may continue to increase for several days, and may keep quite high for a week.

Dr. Kinnicutt, in closing the discussion, directed attention to two points, namely, that many of the preparations of nitro-glycerine were unreliable, and that the physiological effects, as a sense of slight constriction about the neck, a slight intra-cranial fulness, and flushing of the face, should be recognized after the administration of a dose, in order that we might know that a reliable preparation was being used.

The topic of general discussion was the question

"IS ULCERATIVE ENDOCARDITIS ALWAYS A SPECIFIC DISEASE?"

and the discussion was opened by Dr. Thomas E. Satterthwaite (see p. 239).

Dr. W. H. Porter, continuing the discussion, said he had reviewed his records of autopsies, four hundred and fifty in all, and had failed to find one, with possibly a single exception, which could be properly placed under the head of infective endocarditis. In the exceptional case there was extensive ulcerative endocarditis, with softening of the ventricular walls, but the condition was apparently that of old lesions upon which an acute process had been grafted.

Dr. Wesley M. Carpenter said that the paper by Dr. Satterthwaite and the statistics by Dr. Porter showed that the form of endocarditis which the reader called infective was not of frequent occurrence. He was unable to give positive reference, but was able to recall at least two cases of ulcerative endocarditis seen in the autopsy-room at Bellevue Hospital during the last twelve years, and those occurred prior to the days of modern antiseptic surgery, and also during the existence of lying-in wards in that institution.

The lesion in those cases affected the aortic valves prominently, and the exudation upon the valves contained micro-organisms.

Of ulcerative endocarditis affecting the *right* heart he had seen one specimen, presented to the New York Pathological Society by Dr. Ferguson, and another case had been reported in the *Medical News*, but the name of the gentleman who reported he was unable to recall. These were noteworthy exceptions, so much so that one of the gentlemen regarded his specimen as unique. In the light of these facts, based upon observations made at autopsies, additional interest was given to recent articles concerning the essential nature of infective ulcerative endocarditis, and it might not be unprofitable to refer briefly to some of the work which had been done in this direction.

Orth, of Göttingen, reports that he has been able to produce ulcerative endocarditis in animals by first lacerating the aortic valves and then injecting micro-organisms into the circulation.

Ribbert, of Bonn, publishes that he has been able to produce endocarditis by injecting into the circulation the staphylococcus aurens, without first lacerating the aortic valves. Two points in his experiments are worthy of notice. First, to produce any effect, the injection of not less than a certain quantity of cultivated micrococci was necessary, and the best effects were produced when this material was considerably coarse. Second, the results obtained did not affect the aortic and pulmonary valves, but were seen upon the mitral valve, and also in the right heart upon the tricuspid valve. It seems, then, that the ulcerative endocarditis produced in animals artificially by the injection of micro-organisms does not involve the portions of the endocardium in which the disease has been seen by far the most frequently in the human subject.

Dr. E. Darwin Hudson, Jr., related the clinical history of an undoubted case of ulcerative endocarditis, in which there was evidence of long-standing mitral and aortic lesion. In the absence of any definite proof of the specific nature of the disease, the question arises whether degeneration of extensive vegetations is not entirely adequate to produce all the symptoms and determine suppurative results seen in various organs.

The Chairman said that he had been accustomed to recognize *three* forms of ulcerative endocarditis.

1. That which occurs primarily as a simple endocarditis in rheumatic subjects. These patients ordinarily give a history of exudative endocarditis which is not ulcerative, and they are in a depraved general condition.

2. The ulcerative endocarditis which occurs with chronic valvular lesions where we have had evidence of chronic insufficiency or stenosis. These subjects get debilitated, and at the seat of the old lesions ulcers occur, which give rise to emboli and infarctions attended by constitutional symptoms of a typhoid character. In some of these cases recovery takes place.

3. Inflammation at the valvular orifices, or in the endocardium, which results always in suppuration beneath the endocardium, followed by ulcer, emboli, and infarctions, which go on to suppuration, etc. It did not seem to him that there was necessarily anything specific in this class of cases, which were frequently seen in connection with diseases of the joints when the bones are involved. He thought that we should not look so much to the changes in the valves for the cause as to the general condition of the patient in this peculiar form of endocarditis.

Dr. Satterthwaite, in closing the discussion, said that he was very glad that Dr. Carpenter had spoken with

reference to the mycotic origin of the affection, as it was in the direction of what he believed—namely, that the pathologists who claim to have made out this origin have not yet proved their point. He was willing to say this after having read a most carefully written and exhaustive paper on the subject, and in which the author had given a review of what had been done in this field. It could be easily seen that there was no uniformity of opinion as to what kind of bacteria had been seen by different experimenters—one claiming that they were filiform in shape, another that they were round, etc., etc. Experiments had been made with cultivated bacteria, but the results had been that the experimenters had been unable to imitate the disease which occurs in the human subject. He thought, therefore, that physicians would do best not to pay very much attention to the mycotic theory in its present stage, but to adhere to the clinical symptoms, upon which a diagnosis must be made. The mycotic theory was interesting for the autopsy table only.

The Section then adjourned.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, January 4, 1886.

THE PRESIDENT, W. R. BIRDSALL, M.D., IN THE CHAIR.

DISCUSSION ON DR. HUN'S PAPER (SEE p. 221).

DR. E. C. SEGUIN said that in his practice he had frequently derived considerable help in diagnosis from the patient's handwriting. He thought the medico-legal aspect of pathological handwriting might, after further study, assume considerable importance. It would be of value to be able to say in a court of law whether a given specimen of handwriting were that of an aged imbecile, a general paralytic, or an intoxicated person.

DR. LESZYNSKY thought he could hardly say from the specimens of handwriting of paralysis agitans presented that they were characteristic of that disease. He had a number of specimens of handwriting of chronic alcoholismus which were almost exactly similar. Dr. Peckham had not mentioned the handwriting of epileptics, nor had he read of anything characteristic about it, but he could recall two epileptics whose handwriting appeared to be rather unique. In some epileptics there was the condition known as the echo sign, being a repetition of words during conversation. He had seen the same thing manifested in the writing in two cases. He had recently had a case of telegrapher's cramp, in which the movements were remarkably ataxic, being without any control.

DR. PUTNAM-JACOBI had been struck by the great varieties and peculiarities in the handwriting of persons in usual health. Some of the peculiarities supposed to be more or less characteristic of the handwriting of diseased states were also observable in the handwriting of certain persons in a state of health. For instance, Dr. Jacobi was unable, without giving special attention, to write in a direct line across the page; the line always sloped downward. The question had suggested itself to her whether in the case of the insane the tendency, especially after writing for a while, to slope the lines downward and to use capitals profusely, was not due to mental fatigue; and the use of capitals might be due to a desire to emphasize an idea, which a fatigued and feeble brain was incapable of correctly expressing.

DR. DANA said he did not think it would be practicable for everybody to learn short-hand instead of other writing, but he thought some modification of short-hand might be adopted. There would result, perhaps, greater facility of expression if present methods of writing were simplified, but there would no doubt be an increased amount of writing, which perhaps would be a greater misfortune.

Regarding mirror-writing he thought it was physiological. When we educate the centres to write with the right hand, we at the same time educate to some extent the automatic centres for left-hand, or mirror-writing. If a person put a pencil in either hand and attempt to write his own name, he will find that the left hand will write mirror-writing, while from the right hand the usual writing will result. If, then, by hemorrhage the centre for control of right-hand writing be destroyed, it would be perfectly natural for the centre controlling left-hand writing, if not corrected by the will, to produce mirror-writing.

DR. A. B. JUDSON presented a specimen of mirror-writing by a negro girl, eleven years of age, produced ten years ago. She had slight right hemiplegia, but was able to perform household work with her right hand, and she could also write somewhat with it. The writing with the left hand was a fine specimen of mirror-writing.

DR. PECKHAM closed the discussion, and said that the echo sign, the repetition of written words, was well shown in the third specimen presented, that of a woman who had right hemiplegia and amnesic agraphia. Regarding the use of capitals and the tendency to underscore by the insane, she thought it in harmony with their exaggerated ideas.

The Society adjourned.

Correspondence.

"CONGENITAL TORTICOLLIS."

SIR: Seeing in THE MEDICAL RECORD of January 23d an article by Dr. Hadra under the above caption, I send you the history of three cases similar to those there described, with recovery without myotomy. My own child, a daughter, when three weeks old, was found to have a tumor the size of a robin's egg, elongated, in the middle of the left sterno-cleido-mastoid muscle.

The child's head was drawn to the corresponding side. The muscle for an inch and a half above and below the tumor was tense, hard, and tendinous, rather than muscular, to the touch.

Hesitating to subject so small a child to the risks of an operation—always a serious thing in children—although none of the works consulted gave promise of relief otherwise, I submitted the case to an old practitioner, who bade me have no concern, as he had had two precisely similar cases, both recovering without operation.

I resolved to wait, at least, and see, continuing, meantime, the use of simple olive-oil with systematic rubbing three times a day. After four weeks the tumor was perceptibly smaller, and the contraction less marked. At the end of six months both the tumor and contracture had entirely disappeared, and to-day the child, a six-years-old, carries her head as erect as any one.

Such also was the outcome—one in five months, the other in seven—of the two cases described by my adviser.

"If the deformity of a congenital torticollis from contraction of the sterno-cleido-mastoid muscle," says our writer, "is due to a fibrous degeneration," etc.

Is not the question whether there was fibrous degeneration the very point to be decided?

"Degeneration," according to Dunglison ("Med. Dict.," art. Degen.), "is a degradation of intimate constituents." Virchow (ibid.) also uses a similar term, "necrobiosis," to express the same thing; while Conner says ("Inter. Ency. Surgery," vol. iii.): "The changes which may take place in muscular tissue are granular, waxy, fatty, and pigmentary degeneration"—never fibrous. And the facts would substantiate the statement, that the contraction in question, if anything, is not a degeneration, but rather a closely packed bundle of muscular fibre, the result of some intra-uterine inflammation of the sheaths of the muscle, producing cicatricial contraction of those sheaths and the muscle-fibres inclosed. While the results of operations in Dr. Hadra's cases place beyond cavil any other condition than a contraction, the possi-

bility of non-myotomic recovery seems not to have occurred to him.

Rheumatism, spinal malformation, and rachitis are excluded in my cases. The children were delivered by instruments, safely, and without discoverable injury. Granting, however, that the etiology here was traumatic, does it follow that the difficulty was less serious, or operative treatment less imperative? How are we to know, from any examination possible, that the contracture is *fibrous*, and consequently, in Dr. Hadra's words, "not amenable to orthopedic appliances, emollients, or massage?"

"The tumor may disappear," he further says, "but the contraction will grow worse if left alone." Dr. Hadra gives the results of two cases seen by himself, and their successful treatment, in accord with accepted authorities, by early myotomy.

I have given the history of three cases precisely similar, so far as it is possible to determine—the other two differing in no essential from the one detailed above.

These also recovered, and, contrary to the writer's sweeping assertion, *without* operation; and completely, as proven by the lapse of several years with no symptoms of return.

These instances suggest the inquiry: Might not a majority of the cases recorded as operated upon for torticollis have recovered without operation, using massage, and emollients, olive-oil, cosmoline, etc., instead?

We might at least give these little patients the benefit of the doubt, and wait a reasonable time before subjecting them to needless suffering and the dangers attending all operations upon the neck, with their not infrequent sequelæ, septicæmia and death.

This course commends itself the more, since delay in such cases is not dangerous, a crisis is not imminent, and haste, therefore, unnecessary. The operation can be performed at six months as well as, and with less real danger than, at six weeks. Mayhap by that time the scalpel will not be needed.

There ought to be earnest protest entered against this fast growing propensity to indiscriminate use of the knife. To men of experience, whose years of study and observation have brought caution and judgment, Dr. Hadra's advocacy of this heroic method can do no harm. It is otherwise with the beginner. To him there may seem no other remedy or method than the one recommended by Dr. Hadra, as it comes to him while anxiously studying his first case of torticollis. Should we not, although with the present weight of authority against us, say to him: Wait, and in the name of humanity stay the too ready hand, first using nature's remedies, and resorting to harsher measures only when all other resources have proven futile?

Thus only shall we approach the ideal physician—in uncertainty careful, in emergency self-possessed, in danger fearless, in all things honest.

F. D. BROOKS, M.D.

CLAYVILLE, N. Y.

JAPAN AS A FIELD FOR MEDICAL PRACTICE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I am constantly in receipt of letters from physicians in America who appear to consider Japan an El Dorado, inquiring as to the opportunities and prospects for medical emigrants to that country. A similar letter having been referred to me recently, by the American consul here, I indorsed it as below. It strikes me that by its doggerel form it may attract more attention in your columns than would the soberest and most professional statement of the facts, which are nevertheless truthfully put.

I must, however, request that names and exact localities be suppressed. Perhaps a few lines of editorial, as suggested, might do. Yours,

STUART ELDRIDGE, M.D.

The following indorsement, by the consular medical officer, appears upon a letter inquiring as to the laws regulating, and opportunities for, medical practice in Japan, addressed to an American consul in that country by a physician in the United States contemplating emigration. It is evident that whatever Japan may have been in time past, it is no longer a remunerative field for the foreign practitioner.

Respectfully returned. In this Rising Sun Land
There's a law, as elsewhere, of supply and demand,
Which applies unto doctors as well as to corn,
And forbids further import, as sure as you're born.
For the Japs have their own learned dispensers of pills,
And but rarely call *us* to prescribe for their ills;
And e'en when they do, at least when they call *me*,
Send me bad eggs, or sponge-cake, by way of a fee.
As to foreigners here—why, we've doctors enough
For a town thrice its size. Yes, completely *quant. suff.*
Did I say *thrice* its size? 'Twould be much nearer true
Had I made it six times; but then either will do
To explain what I mean, viz.: that doctors are plenty;
In proportion to laymen, say as one is to twenty.
And the twenty—good Lord! but how healthy they are!
And as poor as they're healthy, pleading "no biz" in bar
Of payment of bills, be these large, be they small;
Till in truth its scarce worth sending bills in at all.
"Did you call twenty times, Doctor? Seems to me not;
I never once dreamed that so low I had got.
To be sure I was sick. Once I thought I'd have died
But I might have been cured sooner had you but tried.
The times are so hard, and exchange is so high,
If it wa'n't for the funeral 'twould be cheaper to die.
I'm sure that 'night visit' was made after six,
And yet you've charged double. Well, say that we fix
This bill of yours thus: the amount is so large,
And each visit three dollars! here, here's half of your charge.
You can take it or leave it." 'Tis taken with glee
At recov'ring e'en half of our hardly earned fee;
For the doctor full knows (and the patient as well)
For a doctor to sue sends his practice to—Sheol.
Unless Dr. M——e has good greenbacks galore
To fling to the winds on this far-distant shore;
Or, unless he can live, like old Tanner, on air,
As he's safe in God's country—God! let him stay there.

YOKOHAMA, JAPAN, January 4, 1886.

OPHTHALMOLOGY IN PARIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I HAD hoped to find time to write to THE MEDICAL RECORD from Paris something that would be of interest to physicians. The auspicious moment, however, did not present itself; or, at least, so I fancied, and it amounts to the same. The Christmas holidays, being, like all other holidays, sacredly (?) observed by the Viennese—noted clinicians and all, so wonderfully do the exigencies of suffering mortals adapt themselves to periodical pauses—afford one an admirable opportunity of thinking on unfulfilled promises, provided he hasn't too many other such pleasant things to think about. Unfortunately (for my letter) I am not in Paris, that well-spring of originality in medicine. Fortunately (for me) I *am* in Vienna, a place which every man who can, particularly every medical man, should visit; besides, is not Paris but on the way back to America? It is never so satisfactory, either, to write or to read mere recollections in lieu of coeval things, and the only apology for a Paris letter from Vienna must be sought in the statement made at the outset, coupled with the fact that, while the material is drawn chiefly from memory, the subjects are mainly current ones. Though having as an essential mission abroad the looking up of matters relative to special branches, it certainly were not advisable to neglect the progress of the science in general, nor the noting of many other and quite extraneous matters. But if one expects on crossing the Atlantic to find every method an improvement on those to which he has been accustomed at home, he is doomed to be *most happily* disappointed. If he goes no farther than London, he will probably find nothing so good.

The very first thing by which one is struck on the Continent—which, by the way, is more forcible than pleasant or enlightening—is the bad air of rooms in which clinics of great men are conducted. The Frenchman, be he layman or professional, undertaker or hygienist, has a mortal

aversion to fresh air. The windows of his sleeping apartments are kept scrupulously and hermetically sealed, even on the most sweltering summer night, as otherwise it would be [illegible] to the room. What acts as a preventive of ocular maladies must of necessity be a prime factor in their treatment, so it would seem, for you might hang up your hat anywhere in any room about the Paris eye-clinics. To be sure, that of Professor Panas, one of the very best, held, as it is, on the ground floor of the palatial Hôtel Dieu, has the loftiness of the ceilings and general commodiousness to thank for being almost an exception. I have never seen its windows and doors open. The good result obtained amid such wretched surroundings is one of the strongest proofs of the efficacy of antiseptic medicine. And truly do they stand by the latter. The hateful, impish bacillus is hunted down most unrelentingly. If he lurks about the jaws of scissors or the blades of knives, he is suffocated in a twenty per cent. solution of phenol; if he alights on the site of a proposed operation, he is sponged out of existence with sublimate in water; if he hides in an Eustachian catheter, he is overwhelmed and eaten up by permanganate of potash (1 to 500); and in divers anatomical nooks and crannies, whither he betakes himself for mischief, he is shot dead with powder of iodoform. Not only are surgeons' and assistants' hands always washed in sublimate or boric water, and instruments immersed in carbolic, but these same precautions are religiously adhered to throughout all subsequent interference.

Another thing I cannot refrain from alluding to while it occurs to my mind. It is the tractability of patients in the Old World, particularly on the Continent. Our American freedom and independence, while they are a privilege and attribute in general greatly to be applauded and admired, may be found sadly in the way of those who seek the benefits to be conferred by disciples of the healing art—to say nothing of the inconvenience they may occasion the disciples themselves. All things else being equal, the European physician will ever accomplish the greater good so long as this difference in disposition remains thus in his favor. It is manifest even among the more juvenile classes. Only a day or two ago, I saw a young one of two years hold on tightly with both hands to its nose, while it bore without a whimper the probing and other gouging of an open, ulcerated mastoid.

As for anæsthetics, one who has been accustomed to the uniformly safe and efficient ether narcosis, when carefully conducted, cannot but wonder at the fearful predilection of the men of Europe for chloroform and its scarcely less treacherous admixtures. Fortunately, they evidence a high appreciation of the value of human life in the discretion with which these things are always administered. The almost universal medium is the Esmarch basket. Péan, however, the most taking, if not the most distinguished, of the Parisian surgeons, in his clinic at the hospital of St. Louis, resorts to the complicated apparatus of Junker, or a similarly constructed one. A word just here as to this gentleman (Péan) might not be amiss. The *personale* of the man, though something unique, owing to his appearing always at the hospital clad in a dress-suit, is most engaging, while his cleverness, skill, and the clearness of his demonstrations are nothing short of extraordinary. The costume referred to, if it be an eccentricity, is certainly a happy one. It must be infinitely less suggestive, if not more inspiring, than the butcher-like garb assumed in most instances. The patient, if, as usually the case, an anæsthetic is to be given, sees before him naught more direful than an elegant gentleman, and, accordingly, feels less like a victim. It is only at the moment of commencing the operation that an assistant ties behind the surgeon's neck a large napkin, sufficiently ample to protect his front—and for each case a fresh napkin.

One of the most striking differences thus far noted between methods at home and abroad relates to the extraction of cataract. Professor Panas has long since, in an excellent paper entitled "The Best Mode of Operating for Cataract," expatiated on the prevailing tendency to return to first principles and procedures; and many have come seriously to doubt if Graefe really did so much in this direction as to merit the world of fame he acquired. Take, for example, the clinic of M. de Wecker—his method consists in the following steps: Hands, instruments, etc., having been disinfected, and the sensibility of the eye annulled by cocaine (an anæsthetic is never given), an assistant lifts and fixes the upper lid, while the operator depresses the lower with the forceps by which he holds the eyeball; then, with a miniature model of Graefe's knife, puncture and counter-puncture are made as usual, but, instead of adhering to Graefe's method, he cuts straight out, with startling rapidity, either in sclero-corneal juncture, or slightly within the cornea, so that the incision is essentially that formerly made with Beers' knife. If, then, the iris promises no serious interference with the exit of the lens, he omits the iridectomy. His capsulotomy consists in one vertical incision. Here he takes the upper lid from the assistant with his left hand, and with spoon in right delivers the lens by gentle pressure. After waiting a moment for the accumulation of aqueous, he milks out, by careful manipulation of the eye through the lids, whatever soft portions of lens substance may have remained behind, in a similarly dextrous manner to that of Dr. Agnew. He then cleanses the wound, and, if necessary, replaces the iris; and it is here that his ingenious little hard-rubber spatula does such valuable service. The operation completed, he proceeds to dress the eye by first applying to the wound, with a small spatula, a paste of iodoform and solution of carbolic acid, very much after the fashion in which the plumber lays cement on a joint of drain-pipe. The rest of the dressing is not peculiar. These operations are all performed on a table in one of the ground-floor rooms, and the patients allowed, immediately afterward, to walk up-stairs.

M. de Wecker extracts alike ripe and unripe cataracts, only making for the latter a somewhat larger incision; and, out of some three hundred extractions yearly, acknowledges a most insignificant percentage of poor results. He considers three weeks sufficient time to elapse before the discussion of secondary cataract. The absence of the blepharostat is doubtless an advantage, since those popularly employed are, at best, but bungling and pernicious instruments. That of M. Landolt, which has no horizontal bar to place beneath the lid, and can be readily removed from position with one hand, seems best to meet the requirements. While touching on ophthalmology, much might be said concerning the telling work of the last-named gentleman, as also of the gifted Galezowski; but not wishing to furnish application for the fable relative to hay in a certain manger, I choose to refrain—your space is too valuable. Though, perhaps, if your readers shall ever sufficiently recover, why, in the language of the polished Landolt, "*un autre jour, un autre article.*"

C. H. B.

Vienna, [illegible]

A WESTERN BREEZE.

[illegible] of the Medical Record.

SIR: To be sure the medical profession in our country is in a sad plight. The bells of freedom are ringing out their invitations to the world: "Come and be merry. Here you can practise in an honorable profession without preparation and with abundant remuneration. Carpenters, blacksmiths, and farmers are permitted to prescribe for deadly ailments, receiving professional emoluments for their services." Why shouldn't they accept the invitation so freely given? The change from a London street-sweeper to an honorable American specialist is not an unpleasant one. Indeed, this glorious land of liberty is fast making slaves of us all through this mistaken notion of freedom. But here they come, butcher, baker, and fisherman, of

the poorest class, grasping a bottle and a pill-box, and all will soon be settled as wise European specialists. Who charges them with ignorance? Many patients will recover in spite of their maltreatment. How may the public know whom to choose, when death is inevitable, whether met by a Pasteur or a wonderful Chinese pulse-healer? The latter only makes mistakes, and so do we all. Can we blame an ignorant public for trying the new, when the old has ever failed? True, there are many other reasons for the hard times now being experienced by the medical profession in America. The Rebellion, while it lasted, opened a large field for the doctor. Physicians then made money rapidly, tempting young men to enter our ranks. In fact, the effects of the war in this direction are not understood even yet by hundreds who are just now entering our profession. Again, medical and hygienic literature are being scattered by the idle physician, and read by an increasingly intelligent public, so that thousands of well-to-do families need medical aid much less than formerly. This, of course, is a public benefit, and should not be decried. Hospitals and dispensaries are being located by hundreds. Money is being lavished upon these institutions by the rich; and it has come to pass that a man can often be better treated for nothing than by depleting his own pocket-book. Again, thousands of medical women—accoucheurs and professional nurses—are coming to the front, and are glad to work at greatly reduced rates. They once taught school for three or five dollars per week, and fifty cents for a prescription seems like rolling in riches, compared with their former condition. Another cause lies at the doors of the better class of the medical profession. Even when poor, we dress well, drive fine teams, and dwell in elegant residences. We even borrow money of intimate friends with which to carry on this deception, thus presenting to the young man about to enter business a picture of affluence and independence. We lie to the world by telling them we are doing well when we are doing nothing. By these false pretensions we induce thousands to join our ranks and divide up the already meagre profits. Truly a sad state of affairs! Fools in the profession quarrel, dog fashion, biting off each other's ears and noses. Knights of Don Quixote type shoot their brothers down. Prominent and skilful surgeons, who ought to be crowded with consulting cases, are forced to be constantly on the watch lest they lose a hard-earned reputation. Even in the growing West, where one would naturally expect to find good openings for physicians, financially speaking, every other occupation is superior. The common wood-chopper just over from Europe can save more money than the ordinary professional. Ox-teamsters with good habits often save four, six, and even ten thousand dollars, before forty years of age. I believe very few city or country physicians do better. The poverty of the Polish and the Russian physician stares us in the face unless we can improve our condition. What can we do? Quacks have always existed, and always will, if not legally, by evading the law. They may be exposed and crushed occasionally, but this can only be done by a united profession, such as we are far from being to-day.

The demand for physicians created by the war has ceased; and if we are only honest to the generation about us, and speak out and tell them that we are making nothing, and expect to make less, we may greatly diminish the increasing influx into the profession.

This we believe to be *the* remedy for our troubles.

More instead of less women are to be added to our ranks.

They have come to stay. Who blames them? If they cannot soothe the aching brow of a husband, or a son, they mean to stand by the bedside of the wounded soldier.

Hospitals will continue to draw our best families as long as they receive our skilled services for little or nothing. Patients of means prefer the attendance there to depleting their own pockets. Institutions for the needy poor are humane, but if we wish to eliminate all others we must charge more for services.

Instead of pulling down the skilled and the aged in the profession, as we fear is the rule to-day, we should help them. What we take from them goes often to the quack or to the novice. The struggling doctor of forty hints that the professional of fifty is antiquated in his practice, and in turn the former is soon submerged by his younger followers. If we can crush from the regular profession this selfish disposition, and render a helping hand to skill and experience, feeling sure of like support as we grow old, young men will find less encouragement, and quacks will lose their strongest support.

Then, again, one-horse medical colleges are becoming parasitic in nature, drawing life and energy from the body of the profession.

These are born in every hamlet by a few starving doctors, in order to thrust themselves more prominently before the public. A medical college in a sparsely settled community, with little capital and less talent, is a nuisance, and should be severely let alone. The metropolis alone should support medical schools. If this evil were abolished our better class of colleges would be more independent, receiving better pay for work performed, and able to withhold diplomas from all who are not capable and well instructed. As it is, medical colleges are in the same condition as the profession.

Can we not support our best schools and boycott the remainder?

It is time to act, if our profession is not to degenerate into worse than a trade; financially it is now beneath them all.

Undoubtedly this overcrowded state of affairs is the chief cause of the disgraceful attitude in which our once honorable body of national delegates now poses before the world.

Young men, and men of little experience and less skill, are struggling for existence, and must crowd out those of acknowledged ability and wisdom. Starvation or notoriety are the only alternatives; so the wise, who are few, are pushed aside by the inferior, whose number is legion.

Are there any remedies within reach for our disease? If not, woe unto our honorable body if it continue in the same course of degeneration it now follows.

In the West many of our best men are leaving the ranks for easier and more profitable occupations; more will soon follow, leaving the field to Chinamen and charlatans, unless our standing room can be enlarged.

Surely the cry of the pessimist is not without foundation! Is our diagnosis imperfect? If so, will some one please point out the mistakes. At least let us join hands, study the symptoms, search out the remedies, by experiment, if necessary, and apply them heroically. It is far better for the patient to die than live a life of abject misery.

A WESTERN SUFFERER.

THE MAN WHO IS ALWAYS DOING WELL.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: As you drew us a picture of the bore who always buttonholes you and pours into your unwilling ear the marvels of a very remarkable case I had the other day, there still remains another variety of the *genus homo* to describe. This variety is very common and is found in all climates, but whether he flourishes and grows fat is a doubtful question. This specimen seems to thrive when practice is dull and we have "the blues." He always assails our ears with "never busier in my life," "been going all day," "up five times last night," "had three labor cases yesterday," "old Smith paid me fifty dollars for delivering his wife," etc. What is the trouble with this individual? Are his vagaries to be taken as the early indications of some mental trouble, or does he really believe that he did do

all this, or is he actually in cold blood infringing on the commandment which forbids prevarication? The treatment for this complaint, when in good humor, is no doubt to swallow it, *cum grano salis*, to take away the disagreeable taste and to help its digestion. But when exasperated by dull times what must we do? We know that his "going all day" amounted to his buggy standing two hours before his office and two drug stores, plus the two hours he can take to tell us all this in our office. And as for old Smith, we have been there. We preceded Mr. Smith's previous accouchement, and the generous Smith's account still figures in only one column of our ledger, and if we believe what we hear his account is in unstable equilibrium on other ledgers. I say, what must we do, how must we treat this particular individual? Pray suggest something, for it was only yesterday that one of this genus flaunted a wallet in our face with the accompaniment, "Took in over two hundred to-day." Had we two been alone that wallet should have been ours at the risk of our life, not for its contents, but to show its emptiness. If any of your readers have met with such individuals their method of treatment is most earnestly requested.

Dr. [illegible]

THE PATHOLOGY OF INFLAMMATION.

[illegible] Medical Record.

SIR: In the editorial in THE RECORD of January 30th, concerning a "New Theory of Inflammation," you say, "Despite much opposition, the vascular theory of inflammation still maintains itself as the most satisfactory one yet offered." Virchow's suppuration theory which you refer to as his "inflammatory-stimulus" theory was given to the world in 1855. Cohnheim's migration theory, referred to as his "vascular theory," was made public in 1867. In your brief review of past theories of inflammation you make no reference to Stricker's tissue-metamorphosis theory published in 1869, in which he taught that the cells return to their embryonic state. This theory Stricker modified in 1874, and it was called by him his tissue-metamorphosis theory (see "International Encyclopædia of Surgery," vol. i., p. 27, Pathology of Inflammation). The fact that no reference was made to this theory in your editorial would seem to imply that it has no merit. Believing fully in the uniformity of nature's laws, and that the phenomena of the universe are best explained by the evolution theory, it being the best working hypothesis extant, I hold the opinion that the phenomena of disease, as a part of the phenomena of nature, are best explained by the law of degeneration, which is but a part of the great law of evolution, and that the pathologico-histological changes in all diseases are forms of degeneration.

Stricker defines his theory as a "metamorphosis of tissue; return to the embryonic condition; division into amœboid cells of the masses which have become movable; hence the destruction and the suppuration."

This theory of Stricker's seems to me to be in accord with what is known and taught by our best scientists concerning the law of evolution. Slight modifications of his views may be necessary as science progresses, but in the main I believe his theory will be proven to be true.

Degeneration may be defined as those changes from a higher to a lower form, from the complex to the simple, from the heterogeneous to the homogeneous, in which the organism becomes adapted to less varied and less complex conditions of life, in which there is suppression of form corresponding to the cessation of work. Reversion of structure toward, or to the embryonic state is one of the kinds of degeneration. Not that all degenerations are the exact reversed process of elaboration, but that some are, and the inflammatory process is, in many cases if not in all, this form of degeneration.

Stricker says: "Two features characterize inflammation, viz.:

"1st. An active hyperæmia.

"2d. An active tissue metamorphosis."

In active hyperæmia the blood-vessels become dilated because the stimulus, traumatic agency or influence, has induced an impaired function of the special nerves of that part definitely known as the vaso-motor nerves. That this impaired function of the nerves is a degeneration may be seen by recalling Herbert Spencer's well-known law of development and its converse, viz.: "When a wave of molecular transformation passes through a nerve there is wrought in the structure of that nerve such a change that a like succeeding wave will pass through with greater facility than its predecessor."

It seems to me that the converse of this law must be equally true, viz., when a wave of molecular transformation passes through a nerve with less facility than the preceding wave, there has been wrought in the structure of that nerve a change from a higher to a lower organization, and this is, at least, a temporary degeneration. In corroboration of this view experimental and clinical investigations have proven that these degenerative changes are characterized in the main by diminution and loss of the faradic and galvanic irritability, and this loss of power demonstrated by electricity is characterized as "degenerative reaction." Not that this can be easily demonstrated in inflammation, but that there are good reasons to believe it exists.

Stricker holds that the cardinal symptoms of inflammation, redness and heat, not always being present should be discarded as inaccurate, for when present both are fully explained by the active hyperæmia, the redness by the increased quantity of red blood-corpuscles, and the heat by the accelerated blood-current.

Pain, swelling, and impaired function are explicable only on the hypothesis of tissue metamorphosis.

Pain and visible swelling are not always present in inflammation. The swelling from infiltration and enlargement of the cells Stricker holds to be due to a more youthful condition of the tissues, the pain to tension or laceration of nerve-filaments induced by the swelling, and the impaired function to degeneration of the structures involved. These changes in the tissues are always degenerative at first, and when a stage of retrogression has been reached where cell multiplication can take place, the tissues may then be elaborated into their appropriate mature structure, or they may undergo still further degenerative changes which are destructive in character. Dr. Landerer considers "inflammation a conservative, protective, and reparatory process."

No doubt this is often the case, but not always. The forms of degeneration seen in inflammation are various; they no doubt vary with the nature of the exciting cause, and with the intensity of the inflammation, with the character and extent of the vascular disturbance, and with the nature of the tissue involved.

My object in writing these few lines is to invite attention to the "tissue-metamorphosis" theory of Stricker concerning the pathology of inflammation, and its truth or falsity, and to the value of the law of degeneration as explanatory of all pathological processes.

L. A. MERRIAM, M.D.

[illegible]

CONGENITAL DIAPHRAGMATIC HERNIA. M. Chevalier reports the case of a child born at seven and a half months, with marked ascites, who lived only an hour. At the autopsy, after an incision into the abdomen and evacuation of the fluid, an opening was seen in the middle portion of the right half of the diaphragm, through which the entire right lobe of the liver with the gall-bladder had passed into the cavity of the thorax. The hernia extended as high as the right clavicle, and was covered by a translucent membrane like the peritoneum or pleura. The right lung was compressed and pushed to the left.—*Revue Médicale*, December 26, 1885.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 20, 1886 :

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
February 20, 1886.....	2	7	45	4	6	65	3	0
Deaths.								
February 20, 1886.....	0	2	2	4	1	32	0	0

CLINICAL NOTES.—For dropsy due to anæmia, Professor Da Costa ordered Blaud's pill to be taken. Professor Da Costa frequently prescribes codeia in half-grain doses for cough. Professor Da Costa prescribes the centesimal solution of nitro-glycerine for asthma, commencing with one drop ter die. At Professor Parvin's clinic was a woman who had borne eighteen children at full term. She was accompanied by her sister, who had borne sixteen. Subnitrate of bismuth, mixed with glycerine, as thick as can be used in a syringe, is a capital injection for gonorrhœa (Bartholow).—*College and Clinical Record.*

DR. DA COSTA ON THE MEDICINAL TREATMENT OF DIPHTHERIA.—As to *medicines*, one of the earliest and best treatments is by potassium chlorate, 3 j. to 3 iss. per diem, in divided doses, well diluted. Next to this, either alone or combined with it, is tinctura ferri chloridi, gtt. x. every hour or two, for a child aged ten. The rising treatment now is with calomel. It consists in giving large doses frequently, not minding the free movements from the bowels. Give one grain every hour till twelve doses have been taken, then the same amount every second hour. This has been often tried in the *laryngeal* form, in larger doses, and is of especial utility in this variety of the disease. Corrosive sublimate, gr. $\frac{1}{20}$ to $\frac{1}{12}$ every hour, is a similar but hardly as effective treatment. Jaborandi is a very new remedy in this trouble. The idea is that when the patient sweats well the membrane will loosen. As it is very depressing, it is not safe unless the patient is quite strong. Locally, strong caustics have been abandoned. Cleansing, disinfecting gargles are the modern treatment. Carbolic acid, with borax and soda, may be used. Thymol holds a high place, never weaker than ten grains to the ounce. ℞. Thymol, 3 j. ; glycerini, f 3 iij. ; aquæ, f 5 iss. : M. Sig.—Gargle. Dilute, if necessary. Permanganate of potassium, a favorite with the English, equal parts of lime-water and glycerine, or two parts of the former to one of the latter, are very useful and grateful. When the patient is old enough these are best used in the form of spray. Equal parts of Monsel's solution and glycerine may be used when the redness and swelling are very great. Do not scrape the membrane. The most prominent among the solvents for the membrane are lime, bromine, and pepsine. Of lime it is difficult to get enough. Bromine is too irritating. The remedy that has done best is a saturated solution of pepsine in the form of spray. Lactic acid, jaborandi, and numerous other agents which have been used for this purpose, have some solvent power, but not enough.—*College and Clinical Record.*

SODA AND TEA.—The addition of bicarbonate of soda to tea-leaf, in the proportion of ten grains of the former to an ounce of the latter, has been found to remove almost entirely the injurious effect of tea on starch digestion.

IT NEVER RAINS BUT IT POURS.—The physician of King Alfonso, after having had the misfortune to lose his royal patient, narrowly escaped from the hands of a mob who made an attack on his carriage during the progress of the funeral procession in the Prado. But for the timely interference of the police the unfortunate physician's widow would probably now be meditating upon the fickleness of fortune.

MEDICAL SCHOOLS PROSPERING.—The medical schools of Charleston, S. C.; Atlanta, Ga.; Richmond, Va.; and the University of Virginia, report an unusually large attendance of students. We understand that the medical class of the Tulane University, of this city, is also much above the average.—*New Orleans Medical and Surgical Journal.*

THE SPINNING-WHEEL HAS BEEN PRESCRIBED AS A CURE FOR INSANITY.—It was introduced into the asylum at Douglas, Isle of Man, as something that might amuse the patients, and they forthwith became so interested in it, and in the idea of contributing to their own support by its use, that the direction of their nervous force was changed, and their condition greatly improved. Experiments are to be tried in other asylums.

DR. PLINY EARLE, the retiring superintendent of the State Lunatic Hospital, at Northampton, has a unique scrap-book in which he has preserved two hundred different envelopes received during his administration, spelling his name in as many different ways.—*Boston Med. and Surg. Journ.*

A RIPE OLD AGE.—Dr. Hipolito Fernandez Frutos, of Salamanca, Spain, has recently died at the age of ninety-three years. He was a professor at different times in the Universities of Salamanca and Valladolid, and was greatly esteemed by all who knew him for his intellectual attainments and natural good qualities.

RIGHT- AND LEFT-HANDEDNESS.—A correspondent writes in the *British Medical Journal* as follows concerning this subject : "The functional asymmetry which makes one hand stronger than the other must have some anatomical basis which ought to be discoverable ; but no one yet seems to have detected the cause. Many a time have I gone over the unilateral structures of the body, to consider if any one of them was calculated to influence its own side for good or evil ; but I was always accompanied in my search by this baffling forethought, that if I did succeed in finding some cause for a general excess of muscular nutrition in the right limbs, there would be a corresponding excess of nervous nutrition in the right side of the brain ; an advantage which, by the decussation of fibres, would be transferred to the left side of the body, and things would be equal again. Yet, in spite of this difficulty, I have been continually haunted by the idea that it is in the innominate artery, if anywhere, that we are to find the solution of the mystery. The innominate secures for its own subclavian and carotid those advantages over the subclavian and carotid which arise direct from the aorta on the other side. A tube of a given calibre is more effective than two tubes of half that calibre ; therefore, the innominate, besides serving as a kind of funnel-mouth to catch the stream, is a more effective channel than the subclavian and carotid together would be if arising from the aorta as two distinct tubes. Again, the innominate lies rather more in a direct line with the aorta than do the two equivalent vessels on the other side ; wherefore the innominate would have the advantage of lying more directly in the set of the stream. And the advantage of being a little nearer the heart, even if infinitesimal, is on the same side. Thus the 'bend sinister' of the aorta, and the existence of the innominate artery, tend to increase the blood-supply of the arm and brain on the right side. This fairly accounts for a slight excess of muscular nutrition in the

right arm; and a slight excess, by provoking use, would induce further development. But the right carotid has the same advantage as the subclavian; how is it, then, that equilibrium is not restored by an excess of nerve-force being sent across to the left of the body from the right of the brain? When we observe that ponderous muscular power can coexist with a comparatively small brain, as in the elephant and boa, whereas a large brain with small muscle by no means implies muscular power, it seems fair to conclude that an increase of muscle produces more physical effect than an equal increase of nerve-matter, and that consequently the advantages of the innominate tell more on the muscles of the right arm than on the nerves of the left side of the body. But this only accounts for the superiority of the right arm; what can be said about the remainder of the right side? In the first place, not all the right side is superior to the left; next to the arm, it is mainly in the leg that 'dexterity' is discernible. In the next place, the superiority of the right leg is not nearly so marked as that of the right arm, and may be due to the fact that a sense of power in the right arm inspires a sense of confidence in all else that is right, whence results more frequent use, and consequent development. Also, the advance of the right arm often necessitates the advance of the right foot, as in sword-exercise. But in numerous other cases the left leg, if left to itself, displays a degree of forwardness which excites a suspicion that its inequality is not natural, but induced. I have asked a considerable number of the London Shoe-brigade which foot their customers usually present first, and the replies have been that the left is first presented, almost invariably. The foregoing theory can be easily tested in several ways. Abnormal cases are occasionally noted where there is no innominate artery, the right subclavian and carotid arising directly from the aorta, like their fellows on the other side. I think that one or more such irregularities were observed last year in the dissecting-room of University College, Liverpool. It would be interesting to learn if there were a history of left-handedness in any of those subjects. Also it sometimes happens that the normal position of viscera is reversed, and all the organs are found to have changed sides. One such case is preserved in the College of Surgeons, and within the last few months another was reported from America. Some of the facts connected with right and left are curious and interesting. If one offer the right hand to a European adult, the propensity to extend the right hand in return is so strong as to be almost a reflex action. A Bokhara sheik who suspected Wolff of being a Frank, applied the test of offering him his hand; fortunately for himself, Wolff did not grasp the hand, but responded with a salaam in correct Oriental fashion. But in children this propensity is either not yet developed, or else is overcome by an innate law of least action. I have tried the experiment of offering my right hand to scores of little children; they invariably give the left, which is nearest, and do not cross the right hand over. If I offer my left, they return the right, again swayed by a law of least action. In sliding on ice, my school-fellows used to put the right foot forward almost invariably. Though the word Benjamin means Son of a Right Hand, yet the tribe seems to have been notoriously left-handed. The name may have been euphemistic, like Euonumos and Aristera. Von Miklucho Maclay says that Papuans are always left-handed. I should very much like to know something about the Papuan innominate."

The Diagnosis of Pregnancy.—Dr. Rufus B. Hall, of Chillicothe, O., writes that Dr. E. H. Grandin was mistaken when he said, in his paper read before the Obstetrical Section of the Academy of Medicine, and reported in The Medical Record of January 23, 1886, that an intermittent rhythmical contraction of the uterus, as a positive sign of pregnancy, "is referred to by only one authority (Lusk), and by him very briefly." Mr. Lawson Tait attaches great importance to this sign in differential diagnosis. Dr. Hall writes: "In my presence at the Outdoor Department of the Birmingham Hospital for Women, in December, 1884, Mr. Tait was able by this sign alone to diagnose uterine gestation in a patient that had been sent there by her physician for the removal of what he supposed to be an abdominal tumor. In the fourth edition of his work on 'Diseases of the Ovaries,' p. 211, he says: 'I need not here describe the evidences upon which we base a diagnosis of pregnancy, and shall allude to one only in detail, because it is one but little known as yet; and it is a sign more valuable, perhaps, even than that derived from auscultation, in that it can always be observed, whereas the fetal heart cannot always be heard—I mean the rhythmical contraction of the uterus. If the hands be placed on the abdomen of a case of suspected pregnancy and a fluctuating tumor be felt, that tumor will become quite tense and like a myoma if the examination be prolonged for a few minutes. Then, again, it will become flaccid and fluctuating, and this alternation will go on rhythmically at varying intervals. Once this sign has been felt and recognized, I think it will be impossible for the observer ever again to be deceived by a pregnant uterus.'"

A Chinese Materia Medica.—The work on materia medica of Lee Shee Chan is comprised in forty octavo volumes divided into fifty-two chapters. The introduction, divided into two chapters, fills no less than seven volumes. Then follow three or four volumes of lists of all the medicines used to cure disease, and after this the various articles are taken up singly and treated of in great detail. The last volume is devoted to a learned treatise on the pulse, which is the principal diagnostic aid at the Chinese physician's command. The properties of the articles discussed are considered in a very methodical manner, so that a student can turn immediately to any desired substance, and make himself familiar with its virtues at a glance. Thus the properties of the various parts of a horse are treated of under twenty-four heads, in which the qualities and efficacy of the viscera, hair, hoofs, and other structures are described most minutely.

Physicians' Prescriptions and Druggists' Commissions.—Dr. W. M. McPheeters, of St. Louis, writes: "Professor A. M. Wilder, of San Francisco, in closing a short communication on this subject, says: 'Is this evil confined to San Francisco? Does it not hold true of every large city of the country?' So far as St. Louis is concerned, I am happy to say that no such system obtains here. If it does, I, who have a pretty good knowledge of matters professional in this city, am ignorant of it. I do not believe that any respectable apothecary would offer such a bribe, or that any respectable physician would engage in such petty robbery of his patients." What has Chicago to say to this?

A Genuine Case of Faith Cure.—Dr. Robert T. Morris writes: "Not long ago, while I was seated in a country dentist's office, a farmer dropped in to have a tooth pulled. The tooth came out as hard as a sassafras-root, and the patient pranced around on one foot until the dentist said that he could stop the pain 'if the patient wished.' The patient was willing, and the dentist, taking up a dainty wad of cotton, dipped it in a solution of cocaine, and touched it for an instant to the region of blood, saliva, and pain. Then standing before the patient, with an expression of confident expectancy on his face, asked, 'Is the pain all gone?' The patient gave one glance at the countenance spread out before him, said that the pain had all departed, and began to talk cheerfully on some ordinary topic. Turning to me, the dentist remarked upon the exceeding value of cocaine in dental practice, and said that he believed it would come to be used by the general medical profession before long."

The Orthopedic Section of the Academy of Medicine.—A meeting was held on January 29th, at the rooms of the Academy of Medicine, to organize a section

on orthopedic surgery. Dr. A. Jacobi, President of the Academy, was in the chair. Dr. N. M. Shaffer was elected chairman, and Dr. T. L. Stedman secretary, of the section. Dr. Samuel Ketch read a paper entitled "Remarks on Lateral Curvature, with Special Reference to its Occurrence in Children." The paper was discussed by Drs. A. Jacobi, L. A. Sayre, V. P. Gibney, A. B. Judson, and others.

The Philadelphia Clinical Society.—A stated meeting of the society was held on January 22d, with Dr. E. F. Montgomery, President, in the chair. The following officers were elected for the ensuing year: President, Dr. John B. Roberts; Vice-Presidents, Drs. Clara Marshall and Daniel Longaker; Treasurer, Dr. L. B. Hall; Recording Secretary, Dr. I. G. Heilman; Corresponding Secretary, Dr. Rebecca S. Hunt; Reporting Secretary, Dr. Mary Willits. Dr. John B. Roberts reported a case in which there was a transudation of fluid on the cheek, in the region of the parotid gland, during mastication. On examination of the buccal opening of Steno's duct a muco-purulent fluid was expressed. A probe was introduced for an inch or more into the duct, and the canal was stretched. The following day the patient stated that the transudation was less profuse. The canal was again dilated with the probe, but on neither occasion was a calculus found. The speaker believed the exuded fluid to be saliva, but the patient returned to his home in the country before an examination to determine the fact could be made. Dr. Henry Hartshorne remembered having seen a case of this nature when he was a student of medicine, but he could not say whether the exudation took place only during mastication or not. Dr. Clara Marshall said that Ringer, in his "Handbook of Therapeutics," mentioned a case of excessive sweating of both cheeks, occurring only during mastication, which was cured by the use internally of ten drops of the tincture of belladonna thrice daily. She would not say, however, that in Dr. Roberts' case the fluid might not have been saliva.

The New York Orthopædic Dispensary.—The report of this institution for the year ending September 30, 1885, shows a total of 1,722 patients treated in the dispensary, and 48 cared for in the wards. There were 38 deaths in the outdoor department and 1 in the hospital. Six hundred and sixty-four braces were supplied to patients, in addition to plaster-of-Paris, felt, and other temporary forms of apparatus. The days of hospital care were, for free patients, 6,538; for paying patients, 1,437; total, 7,975. There were 10,252 visits made by patients at the dispensary, and 768 visits made by the surgeons at the patients' homes. The managers are very desirous of making the hospital department wholly free, and they appeal to the charitably disposed to aid them in attaining this end by endowng one or more beds, or by becoming annual subscribers.

The Penalty for Malpractice in China.—For engaging in the practice of medicine in China no license is required, but the lot of the unsuccessful physician is not one to be envied. The following is the two hundred and ninety-seventh section of the penal code which deals with these unlucky practitioners: "Whenever an unskilful physician, in administering medicines or using the acupuncture needle, proceeds contrary to the established forms, and thereby causes the death of the patient, the magistrate shall call in other physicians to examine the medicines or the wound. If it appear that the injury done was unintentional, the practitioner shall then be treated according to the statute for accidental homicides, and shall not be allowed any longer to practise medicine. But if he have designedly departed from the established forms, and have practised deceit in his attempts to cure the malady, in order to gain property, then, according to its amount, he shall be treated as a thief; and if death shall ensue from his malpractice, then, for having thus used medicine with intent to kill, he shall be beheaded."

Priority in Yellow Fever Inoculation.—Dr. Freire, of Brazil, is generally credited with having been the first to conceive the idea of inoculation as a means of prevention of yellow fever. But Dr. Carmona y Valle, of Mexico, claims the honor of precedence, having published an article on this subject in the *Gaceta Médica*, the official organ of the Academy of Medicine of Mexico, on October 26, 1881. The latter has very recently published an exhaustive monograph on yellow fever, dealing especially with the etiology and prophylaxis of the disease, which is a most valuable addition to the literature of this subject.

Vaccination in China.—It is stated by Mr. E. C. Bridgman that vaccination was entirely unknown to the Chinese until introduced in 1805 by Mr. Alexander Pearson, surgeon of the East India Company, who both vaccinated numbers himself and wrote a small tract in explanation of the theory and art. This tract was translated into Chinese by Sir George Staunton. From that time an efficient vaccine establishment was maintained at Canton, first under the care of Mr. Pearson, and subsequently under a native gentleman, He Qua, who was initiated and well instructed in the business by the founder of the institution. From Canton the practice spread into several, if not most, of the provinces of the empire, and the explanatory tract was also widely circulated, although the Chinese publishers took very good care to suppress all evidences of its foreign origin in order not to offend the prejudices of the natives.

Coryza of the New-born.—Dr. Semchenko claims to have obtained excellent results from the use of cocaine in infantile coryza. He instils two drops of a two per cent. solution into the nasal cavity six times a day, and says that four days usually suffice to obtain a perfect cure.

Vomiting of Pregnancy.—Dr. Federico Léon reports, in the *Gaceta Médica Catalana*, a case of obstinate vomiting of pregnancy, which, after all the usual remedies had been tried without success, was promptly relieved by rectal injections of hydrate of chloral.

Treatment of Cardiac Dyspnœa.—M. Sée recommends the following formula: Tincture of iodine, one-half drachm; syrup of horse-radish and syrup of poppies, of each two ounces. Three teaspoonfuls or more may be given per diem in cases of dyspnœa associated with heart disease. The syrup of horse-radish disguises very effectually the taste of the iodine.

Umbrellas and Abdomens.—A certain man in Bavaria, whose ordinary occupation was that of repairer of umbrellas, was consulted in a friendly way by a woman who had an intra-abdominal tumor. He said he could repair her just as well as he could an umbrella, and accordingly, his wife assisting, he cut open the poor woman's abdomen with a razor, found a tumor, cut that out, and then sewed up the wound and smeared it with some "healing salve." The woman did not do as well as an umbrella would have done under similar circumstances, and it was found necessary to call in a physician. The latter caused the arrest of the would-be surgeon and his wife. The patient is now improving.—*Allgemeine Medicinische Central-Zeitung.*

Death of Dr. Dechambre.—The death is announced of M. Amédée Dechambre, editor-in-chief of the *Gazette Hebdomadaire de Médecine et de Chirurgie* and of the medical encyclopædia which bears his name. The cause of his death was cerebral apoplexy. He was seventy-four years of age, but was in the enjoyment of excellent health at the time of his seizure.

Diaphoretic Boluses.—The following combination is said to be useful: Sublimed sulphur and bitartrate of potassium, each thirty grains; powdered resin of guaiac, fifteen grains; to be divided into four boluses. These may be taken at intervals during the twenty-four hours when it is desired to maintain a more or less profuse diaphoresis.

SOME SURGICAL POINTS IN THE TREATMENT OF PERITYPHLITIC ABSCESS.[1]

BY WILLIAM T. BULL, M.D.,

NEW YORK.

THE following case, in which a perityphlitic abscess was opened only forty-eight hours after the symptoms became acute and the patient took to bed, will serve as an introduction to the remarks I have to offer on the surgical treatment of this disease.

CASE I.—On December 5, 1885, I visited with Dr. Kinnicutt a gentleman, thirty years of age, who was suffering from very severe pains in the right iliac fossa, radiating down the thigh, with a temperature of 103° and pulse of 120. The abdomen was normal on examination except in the right iliac region, where over an area two inches square there was dulness and exquisite tenderness (so that percussion was very unsatisfactory), and a sense of fulness or increased resistance on palpation. These were the only signs of an exudation. He had been in bed but forty-eight hours, although for ten days previously he had experienced a steady dull pain in the inguinal region, with occasional paroxysms which were more severe. He was constipated for a week during this time, but the bowels moved naturally three days before I saw him. His symptoms were not sufficiently acute to deter him from a week's railroad travel, and on his return from this they presented the features mentioned above

Dr. Kinnicutt had suggested exploration, and it was done at once. The needle, thrust to a depth of three inches directly backward into the iliac fossa, produced no pus; nor was any obtained when it was thrust in front of and behind this site. A longer needle was then pushed from a point behind and above the anterior superior spine, toward the middle of the fossa, a depth of four inches, and through it the syringe drew some very offensive and bloody pus. The incision was made a few hours later, under ether, above and to the outer side of the middle of Poupart's ligament. The tranversalis fascia was thickened and grayish in color, the muscular layers absolutely healthy in appearance. An incision through the fascia evacuated about an ounce of pus, very dark from blood, and of characteristic odor. No foreign body escaped, and as the time of operation was so early I did not deem it wise to thrust the finger into the abscess cavity; but an elastic bougie showed that it extended from the centre of the incision about two inches toward the symphysis and three or four toward the lumbar region. The pain and fever disappeared next day. The rubber drain was removed on the tenth day, when the cavity was reduced to a sinus four inches deep, extending toward the loins. This was slow in healing, though its orifice was dependent in the erect position. A foreign body was detected in it at a depth of three inches, at the end of six weeks, and removed with dressing forceps. It proved to be a calculus, doubtless formed in the appendix. The sinus closed in a week. The concretion is as large as a white bean, calcareous in composition, the salts being arranged in concentric laminæ, and with no foreign body as a nucleus. Chemical examination has not yet been made.

In this instance the operation was performed at an earlier moment than in any case that I have seen recorded, and I think that the thorough exploration with the needle and hypodermic syringe was the chief factor in bringing it about. I have several times withdrawn pus from the iliac fossa, through a puncture made from the lumbar region downward and forward toward the middle of the iliac fossa, when punctures directly into the fossa or the tumor occupying it were fruitless. A good-sized needle is indispensable (No. 3 or 4 of the French scale for urethral instruments), and a "tight" syringe. These punctures are harmless, and should be made into the lumbar region as well as the iliac fossa. We are all familiar with their value as a means of diagnosis, but I would like to emphasize the advantage of making such thorough explorations as I have described.

But I desire to claim something more for the needle, and that is, that it is the only trustworthy means of ascertaining the presence of pus. Both the general symptoms and the local conditions mislead us in this respect. There are patients who are attacked with high fever, severe pain, chill, and even sweating, whose inflammation undergoes resolution; and there are others in whom the abscess reaches great proportions with trifling disturbance.

Dr. Robert F. Noyes, in a paper read before the Rhode Island Medical Society in 1882,[1] mentions a case reported by Dr. Edson, where the formation of abscess was "indicated by chills, pointing, and a temperature of 103.4°. The case terminated suddenly by absorption. There was no discharge from the rectum, and no external opening." In the following case I was lulled into a feeling of security by the absence of constitutional symptoms, and allowed a week to elapse before making an exploration with a needle, while an abscess of huge proportions was present all the time.

CASE II.—On August 28, 1885, I saw with Dr. U. G. Hitchcock a gentleman, aged fifty-nine, who had been sick for six weeks. His illness commenced with chilly sensations, fever, and slight pain in the iliac fossa, where there was found tumefaction. There was constipation, and the symptoms continued till, at the end of about two weeks, he was relieved of a mass of impacted fæces. Then he improved so as to be able to walk about, but there remained a slight pain in the iliac region, an evening temperature of 100° to 100½°, pulse of 90 to 100, and on my first visit there was a distinct tumor in the iliac fossa, not very tender, not fluctuating, giving dulness over an area as large as the palm of the hand. The abdomen was elsewhere normal, the abdominal wall over the tumor not involved, and the bowels moved naturally, and only a dull pain was complained of. But there had been no improvement for some days, and the general debility was sufficient to keep the patient in his room. I advised waiting a few days before making an exploration. A week later the condition was unchanged. A large hypodermic needle was introduced through the same puncture, thrust backward toward the brim of the pelvis directly downward, and also forward toward the symphysis. From the latter situation a syringeful of pus was drawn. The following day through the usual incision, three inches long, an abscess was opened, which contained at least a pint of pus. Its cavity reached forward beyond the line of the rectus muscle and backward into the connective tissue behind the ascending colon. There was no foreign

[1] A paper read before the Practitioners' Society of New York, February 5, 1886.

[1] Transactions of the Rhode Island Medical Society, 1882.

body seen. It healed completely in two months, but the patient was much prostrated in the fourth week by a pleuro-pneumonia of the right lung. This was succeeded by an arthritis of the first right metatarso-phalangeal articulation and a periostitis of the right eighth rib, from which he is slowly recovering.

These considerations lead to this conclusion: That in perityphlitis the general symptoms and the local conditions may furnish valuable indications of the presence of pus, but thorough exploration with the needle is the best means of diagnosis. Dr. Sands,[1] in 1880, expressed the same view. "Everything depends on an exact diagnosis, . . . and I would suggest a more frequent employment of the aspirator, as affording the most reliable test at our command for purposes of diagnosis."

Opening into the bowel has generally been followed by recovery; but it is sometimes followed by external opening, or burrowing of the matter into the lumbar region, or into some viscus as the bladder, for instance. In a collection of 67 cases which I made for an inaugural thesis in 1872 (*New York Medical Journal*, September, 1873), I found 15 in which the abscess burst into the cæcum. In 10 the cæcum alone was invaded, and 9 recovered. In 5, after the discharge into the bowel, external opening occurred three times with two deaths, and once into bladder, and once into bladder and externally as well. The two last cases recovered.

This tendency of the pus to burrow has not been seen after external opening by operation. The sinus left is stated by all writers to have closed promptly. In view, then, of the liability to continuance of the suppuration after a discharge of pus has taken place from the bowel, I would urge the wisdom of keeping careful watch over these patients, and to explore the lumbar region promptly and repeatedly with a needle, if the general condition do not improve; and I find in the uncertainty of the result after opening of the abscess into the bowel another argument in favor of the operation at the earliest possible moment.

The following case is one in which a large lumbar collection, which gave rise to dangerous symptoms, followed two discharges of pus per rectum. The local signs of abscess were quite masked by the presence of gas in the abscess.

Case III.—A gentleman, aged sixty, rather corpulent, with thick abdominal walls, was attacked February 28, 1883, with violent pains in the abdomen, a sharp chill followed by a temperature of 107°, and sweating. He was constipated, and vomited a number of times. The following day the vomiting stopped, the fever fell to 103°, there was general abdominal tympanites, the constipation continued, and the pain became located in the right iliac fossa, which was tender. There was no tumor. I saw him with Dr. George E. Moore, and called Dr. Kinnicutt. We regarded the case as one of perityphlitis, or typhlitis from impaction of fæces. With rest in bed, opium, and a mild laxative, there was marked improvement after a few days. The pain remained, but was less severe, the fever was only 100° at evening, the bowels moved, and on the tenth and twelfth days there was considerable pus in the stools. All the local signs of inflammation in the iliac fossa disappeared. Between the twelfth and seventeenth day, however, he grew worse. The fever remained about 101° in the evening, with a rapid pulse, and occasional delirium at night. The tongue was dry and furred, and the prostration extreme. No vomiting occurred, and the bowels acted after calomel was given; but the tympanites was very great. Locally there was nothing abnormal to be elicited save a slight tenderness in the lumbar region, and a suspicion of œdema of the subcutaneous tissue. Once or twice the integument showed a patch of erythema, which disappeared in a few hours. On the eighteenth day Dr. Draper saw the patient, and we made a puncture with a *small* aspirator-needle, which showed nothing. Through a large needle stinking pus was withdrawn. An incision was made on the nineteenth day, horizontal in direction, and nearer the crest of the ilium than the ribs. About two pints of pus came away, with several connective-tissue sloughs two or three inches in length, but no concretions. The cavity of the abscess extended nearly to the symphysis. With drainage and irrigation with weak carbolic solution it healed completely in four months. For a week or ten days fæces in small quantities escaped through the sinus.

The necessity of opening the abscess early—and long before fluctuation has occurred—has been insisted on with justice by a number of writers. I have but one suggestion to make on this point, and that is that in determining the *time* to operate, the *duration* of the illness should play a rôle subordinate to that of the results of exploration with the needle. It is certainly undesirable to operate too early, when the pus may not have formed, or the inflammation be going on to absorption. It is equally undesirable to defer the incision and subject the patient to the risks of an unfavorable course on the part of the pus. A sort of "time allowance" has been fixed by some surgeons. Gouley fixes the seventh or eighth day as the proper time for incision; Weber, "not beyond the ninth or tenth;" Sands,[1] from the twelfth to the eighteenth day. From this discrepancy it is obvious that the "time allowance" is of no use, and that it will be far wiser to be guided by the evidence afforded by *needle exploration*.

It may be well to mention the results of Dr. Noyes' investigation of one hundred cases of abscess, treated by incision, as the paper may not be accessible to all. Of these one hundred cases, eighty-five per cent. recovered. The mortality was but fifteen per cent. In the sixty-seven cases collected by myself in 1872, where no early operation was done, the mortality was forty-seven per cent.

I have yet to hear of a single operation which has led to bad results. Even when no pus was found, the incision has proved of use in relieving the pain and fever, and diminishing the tension, and directing the course of the pus toward the surface. Several such cases have been reported. In one instance I found pus with the needle, but could find none on incising the abdominal wall, and none appeared subsequently, except from the wound.

Case IV.—On January 27, 1885, a boy, aged seventeen, was admitted to my wards at the New York Hospital, who, two weeks before, had been suddenly taken with pains in the abdomen and vomiting. This was followed by fever, and there was great pain in the right iliac fossa and lumbar region. The bowels were regular, and the appetite good, but the pain and fever continued in spite of medical treatment. When admitted he had pulse, 120; temperature, 103° F., and the region just above the crest of the ilium on the right side was tender and painful. The abdominal wall was normal; there was no bulging, but an increased sense of resistance on palpation, and dulness on percussion between the crest of the ilium and the free margin of the ribs. There was trifling œdema of the subcutaneous tissue. A hypodermic needle was introduced just behind and above the anterior superior spine of the ilium, and a half-drachm of very offensive pus drawn out. Under ether an incision three inches long was made, parallel to the iliac crest and down to the peritoneum. Several punctures of this membrane in different directions discovered no pus. The wound was stuffed with iodoform gauze and carbolized fomentations applied. The following day there was no more pain, the temperature fell to the normal, and even the swelling and tenderness were not perceptible. No matter was discharged in the stools. The wound healed in two weeks and a half.

[1] Annals of the Anatomical and Surgical Society, [illegible]

"In this case the change in the patient's condition after the incision was most marked, and I see no reason to criticise it. In fact I feel convinced that in the aggregate of cases more good than harm would be done by an early incision, even if the needle detected no pus, provided only that the surgeons were led on by the indications furnished by the general and local symptoms.

Attention has been called by Dr. Burchard, of this city, to the cases of perforative typhlitis in which the cavity of the peritoneum is invaded early, with fatal result. Laparotomy has been rightly considered desirable in such cases. The following case bears on this matter.

A laborer, aged twenty-five, was admitted to my service at the New York Hospital, in this condition. His pulse was 120; respiration, 30; temperature, 103°, with considerable general tympanites and great pain referred particularly to the right side and iliac fossa, and radiating down the thigh. The right iliac fossa was very tender and offered an increased resistance on palpation. It was not dull. Two days before he had a chill, followed by high fever, and vomiting. He was constipated, but the bowels had moved once after an enema. The needle detected pus only in the lumbar region, where there was no tenderness. An incision was made there down to the very wall of the colon, and but a drachm of offensive pus found behind the colon. The finger was not introduced, but a probe, and a bougie as well, did not detect any softened tissue in any direction farther than an inch. The symptoms of general peritonitis persisted, and he died in two days. The autopsy disclosed a general suppurative peritonitis, perforation of the appendix in two places near the cæcum, and fæces in the connective-tissue or the iliac fossa, which was softened and necrotic as far up as the liver, but not yet broken down so as to form much pus, *and nowhere communicating with the peritoneal cavity.* The incision fell in the middle of this tract. In this case inflammation of the peritoneum, and of the connective tissue of the iliac fossa, must have been nearly coincident; and it is doubtful in my mind, since the process had involved so large an extent of tissue, if any operation would have effected a cure. But if a similar case should occur to me again, I would certainly pursue the investigation at the time of operation to the point of seeing the appendix and ascertaining its condition. I am supported in this conviction by the evidence of a somewhat similar case under the care of Dr. Richard Wiener, in which, after the symptoms of perityphlitis had lasted a day or two, those of general peritonitis supervened. The patient, a boy, aged fourteen, lived three weeks. On autopsy there was found general peritonitis, and an abscess behind the cæcum and ascending colon, which contained a pint or two of fluid fecal matters. The appendix was perforated in two places, but there was no communication between the abscess and the peritoneal cavity.

THE PREVENTION OF MAMMARY ABSCESSES.—Occasionally one is called to cases where abscess is on the point of forming, either from neglect or injudicious treatment, and where, consequently, something more is required. Under such circumstances, Mr. Philip Miall (*British Medical Journal*, November 21, 1885) states that he has repeatedly seen all the symptoms of a hot, heavy, inflamed breast, with redness of skin, throbbing and deep-seated pain, pulse being 120 in the minute, all disappear in the course of a few hours under fomentation of hot water and ammonia. An ounce of carbonate of ammonia is dissolved in a pint of boiling water, and when solution is effected the temperature will scarcely be too high for fomentation with cloths dipped in the liquid. These must be assiduously applied for half an hour at least, and repeated for two or three hours if necessary. It is well to protect the nipples, though Mr. Miall states that he has never known them to be injured. Relief is immediate, and more than three applications are seldom required.

THE MANAGEMENT OF BREECH PRESENTATIONS.[1]

By ROBERT A. MURRAY, M.D.,

[illegible] NEW YORK.

ALL writers in obstetrics admit that the mortality in breech presentations is great, very much greater than that of cephalic, and equalling that of the much less frequent presentation of the face. Up to the time of Ambrose Paré the presentation of the pelvic end of the fœtal ovoid was looked upon as preternatural, and cephalic version was always performed. Naegeli has, however, well shown that though attended with much danger to the child the risk to the mother was not greatly increased, and that the mechanism was strictly analogous to that of the vertex.

The pelvic extremity offers at the superior strait about once in 35 cases. Naegeli says that out of 100 labors 94 or 95 present by the head, 4 by the pelvis.

Dr. Rigby, in an analysis of 71,578 cases, found the breech present once in 78 cases, the feet 1 in 105 cases; the mortality of the infant 1 in 3.8, when the breech offered entire; when the feet were first it was 1 in 2.8.

The statistics of Madame La Chapelle show that in 804 presentations of this class 102 children are born feeble, and 115 are still-born, a large number of the former dying shortly after birth; the proportion of deaths to the whole being rather more than one-seventh, while in 266,698 vertex positions there were only 668 still-born, which gives one in thirty. When the buttocks advance first the number of deaths is 1 in 8½, feet presentations 1 in 6½, and for the knees 1 in 4½, or not quite one-fourth.[2] The breech may present entire, or one or both feet descend, the knee may also present, though that is very rare. When, at the beginning of labor, before the os is fully dilated, the presentation of the foot occurs, the results are unfavorable.

Professor Dubois, in an analysis of 80 cases observed by him, found 54 ordinary, and 26 in which the feet descended in advance, the presentation of the knees not being seen once.

The causes we find stated for the presentation of the pelvis are: contractions of the pelvis, excess of liquor amnii, allowing of great mobility of the fœtus, violent movements on the part of the patient, and peculiar formation of the lower segment of the uterus. It is remarkable the frequency of these cases in premature labor and multiple pregnancies.

Professor Simpson, from the observations of Dubois at the Maternity Hospital, has constructed a table, showing the presentation of the child at different periods of pregnancy which illustrates this point.

Period of Pregnancy	Total [illegible]	Presentations. [illegible]	[illegible]	Head
Before end of sixth month.....	121	5	32	84
During seventh month	113	6	34	73
During eighth and ninth months.	60	2	22	36
At full term.....	18	1	3	14

Those stated in the third line only represent cases where the child was born dead, and show how frequently, the child being dead, the loss of the tonicity of the spine and flaccidity of the tissues causes malpositions.

From this table Professor Simpson demonstrates that there is a constant tendency after the sixth month of pregnancy for the head to present.

From the statistics of Hegar and Spiegelberg, of 33,264 children 910 were the result of multiple pregnancy, and 659 were premature; of the former 227, or 25 per cent., and of the latter 148, or 22.4 per cent., were delivered by the breech, though the general average of breech pres-

[1] Read before the [illegible] New York Academy of Medicine, February [illegible]

[2] Cazeaux and Tarnier, [illegible]

entations to the entire number of births is only 2 to 2.5 per cent., or about 1 in 40.[1]

The breech, composed of the nates, feet, and knees, may present, according to Naegeli, in two primary positions, the dorso-anterior and the dorso-posterior, the latter less frequently than the former. Of 161 cases occurring at Heidelberg, 121 were dorso-anterior, 40 dorso-posterior.

The positions of the breech are analogous to those of the head, the sacrum being at the brim in generally one of four positions. The dorso-anterior with the left hip to the front and right, the sacrum to the left acetabulum, the right hip to the left posteriorly, the long diameter (bis-ischiatic) of the fœtus in the right oblique of the mother's pelvis is the most common, and is generally classed as the first position. Succinctly the mechanism is: First, under the influence of uterine contractions the breech molds to the contour of the brim, and very gradually dilates the cervix, the long bag of waters formed by the irregular character of the breech being very inefficient in this duty, so that the first stage of labor is usually very protracted. The breech now descends to the floor of the pelvis, the left hip being rotated to the pubic arch by the guidance of the right anterior ischial plane, while the right hip is guided to the hollow of the sacrum by the left posterior ischial plane. The child bends in a sigmoid form on its left side, the right hip is forced to the vulva and, unless the perineum is unusually resistant, is born first, the left hip being retarded by pressure on the pubes. The body now descends, and with the extension of the lower limbs is born. The shoulders descend in the same oblique diameter, perform the same movement of rotation, and from the arrest of the left shoulder at the pubes the right shoulder is caused by the pains to sweep over the perineum. The arms not infrequently at this stage slip up during the birth of the trunk, and are disposed at the side of the head. If the pelvis be contracted, or the head be not thoroughly flexed on the sternum, this is particularly likely to occur, and the arms may then be found behind the head on the back or neck, and cause a serious obstacle to delivery. The head descends in the right oblique diameter, performs the opposite rotation to that of the breech, turning from left to right under the arch of the pubes, the sub-occipital point becomes fixed, and under the influence of powerful uterine contractions, and particularly contractions of the voluntary muscles of the floor of the pelvis and vagina, the forehead is extruded over the perineum. Since the propulsive energy of the uterus acts at great mechanical disadvantage on the head, it is difficult to see how, but for the contractions of the vagina and pelvic floor, any pelvic labor could possibly be completed without the interference of art.

The second pelvic position being dorso-anterior is similar to the first, the rotation being, however, in the opposite direction.

The third position being dorso-posterior with the sacrum to the right sacro-iliac synchondrosis differs in its mechanism from the first and second in the greater rotation needed to bring the right hip and occiput to the pubes, which is the natural termination. Failing in this, the occiput rotates to the hollow of the sacrum, causing the labor to be prolonged and difficult. If the head descends without interference, the pains being strong and the pelvis large, the occiput is retarded by the perineum at the outlet, the chin, forehead, and face are forced out by a movement of flexion, the back of the occiput pressing on the perineum as a fulcrum. In rare instances the chin is caught on the back of the pubes; the head is then delivered naturally by a process of extension, the depression in front of the neck being the fulcrum; the occiput passes over the perineum, followed by the vertex and face.

The fourth position is analogous to the third, and generally is converted into the first as the third was into the second; but the same rotation of the occiput into the hollow of the sacrum may occur.

The management of the ordinary breech presentation consists in the first stage in the delaying, as far as possible, of the rupture of the bag of waters, so that the cervix may dilate fully to the size of the breech, and especially become soft, yielding, and dilatable.

This may be accomplished by avoiding unnecessary examinations which cause powerful voluntary contractions, and the finger-nail may lacerate the membranes. The membranes may be supported, and at the same time the vagina dilated by a full-sized Barnes' dilator or a Braun's colpeurynter in the vagina. As long as the breech descends we do not interfere, as the more full the dilatation of the parts the safer and more rapid will be the subsequent passage of the head. So soon as the trunk and lower limbs are born the critical period for the child approaches. Compression of the funis by the hard, unyielding head against the pelvic wall is likely to occur, and if complete and continuous, rapidly destroys the child by interrupting the placental circulation. We should now pull down a loop of the cord and pass it to the sacro-iliac synchondrosis at the side of the child's head. The child's limbs and trunk should be enveloped in a warm cloth and the pulsations of the cord watched; if interrupted or feeble in its pulsations we must immediately relieve the pressure, or the child will be lost.

If the head descends properly, and the pains are strong, we support the trunk with one hand and follow the uterus down with the other, making slight pressure to excite the uterus and voluntary muscles to contraction. The flexion of the head may be aided by raising the trunk upward. The arms are generally liberated in advance of the head.

If the pelvis be ample, the child premature or below the average, and the pains strong, the labor is not difficult; in fact, excepting a retardation of the head at the perineum, it is generally rapid, but if the child is mature and well developed a breech labor is by no means easy.

The difficulty arises from the nature of the presenting part, the condition of the uterus, and the position of the child. There are two principal conditions of breech presentation where the labor may become arrested or difficult.

Whether the position be dorso-anterior or dorso-posterior, the legs of the child may be disposed in two different ways. In the most common case, the legs flexed on the thighs approximate the feet to the nates, so that they become readily accessible; in the less frequent case, the limbs are extended upward over the front of the child so that the toes are near the face.

The breech is not nearly as large as the head, and though, as Madame La Chapelle states, its softness enables it to mould better to the brim, yet this very fact diminishes its dilating power over parts through which a larger body, the head, must pass. Indeed, the fœtal ovoid may be looked upon, as Prof. Barnes in "Obstetric Operations" (p. 173) well states, as a wedge. The breech, forming the apex of the wedge, does not open the cervix widely enough to let the base, formed of the head and arms, which often exceeds the capacity of the brim in mere bulk, to pass. Again, the rotation of the child on its long axis is difficult. The condition of the uterus must also be considered. The cervix only dilates proportionate to the body traversing it. The uterus contracts firmly on the parts in its cavity, but as the base cannot descend, a state of spastic rigidity in the cervix ensues, which, encircling the wedge about its middle, tends to lock up the head and impede both descent and rotation. A condition of inertia is also likely to be present.

If traction be now resorted to by means of hooks, the fillet, or forceps, and unsuccessfully, as it is likely to be, the apex is dragged into the pelvis, the cavity more tightly filled, the compression of the cord is increased, and the uterus has become more irritable. The only safe means

[1] Spiegelberg: Lehrbuch der Geburtshülfe, p. 140.

for the child and mother out of this difficulty is to bring down the foot.

The use of the blunt-hook is difficult ; it is apt to slip out of the groin on to the thigh, and fracture ensues on traction, it contuses the soft tissues and may lacerate the femoral vessels. If the child be living the blunt-hook should not be employed.

The fillet (formed of a skein of silk or a silk handkerchief) may be guided up over the groins by an elastic catheter or by Bellocq's sound, and affords a good hold for traction, but it may also cut into the tissues, and is not powerful enough to overcome the difficulty. The use of the fingers in the groin, as recommended by Smellie, a procedure of much service when the breech is low in the cavity, or to overcome the resistance of a rigid perineum, is of doubtful utility.

The obstetric forceps has been recommended, though condemned by most authorities. Hohl says the obstetric forceps to the breech is neither necessary nor effectual. Professor Lusk[1] says : The experiences of Hueter and Hooke have been favorable, though the latter only advises it where the breech is detained in the cavity, or at the outlet by the perineum." The forceps is designed only for the head, its cephalic curve does not adapt it for traction on the breech, and may injuriously press on the abdominal viscera.

The performance of cephalic version, as recommended by Spiegelberg, in the interests of the child, would only be possible in the first stage, before the waters had ruptured, and before the breech had become wedged in the brim or cavity. Even moderate contraction of the pelvis would contra-indicate it, since Professors Simpson and Thomas have demonstrated that the head can pass through the pelvis with less difficulty when brought down base first, this being due to the lateral pressure on the mobile parietal bones, causing the sutures and fontanelles to overlap and collapse. Again, Professor Barnes has shown that in head-last labors, with any contraction of the pelvis, the head is rarely or never seized in its widest transverse diameter, but at a point anterior to its greatest width, that is, in the bitemporal diameter, the biparietal and occiput finding ample opportunity for moulding in the freer space left at the side of the promontory. It may therefore be considered as demonstrated that the head coming base first passes the contracted brim more easily than coming crown first. And if the head comes through more easily it may be inferred that the child has a better prospect of being born alive.

These observations I believe are pertinent to all head-last labors.

To make an error in mensuration of a mother's pelvis, or the presence of a little larger sized child than the average, would in many cases condemn the child's life by craniotomy, after failure with the forceps, when the proper treatment might have saved it. I have seen many cases lost by the delay incident to the employment of these measures, before their inefficiency was demonstrated. I have never needed to apply the forceps to the breech at the brim. The clear indication is to break up or decompose the obstructing wedge. This is done by bringing down one foot.

Having determined the position of the breech in relation to the pelvis by the ordinary diagnostic points, sacrum and anus behind, the genitals in front, and the ischiatic protuberances on either side, the hand is passed into the os uteri in front of the breech, where the feet lie. Seize one by the instep and bring it down. Generally the breech will soon descend. One foot is all that is necessary, as the breech still retains its rotundity and the cord is better protected than when both feet are brought down. The foot nearest the pubes is the best, as traction, if necessary, can more easily be exerted. If the case be not urgent from other complications it may now be allowed to proceed naturally. Where the feet are extended up to the face over the front of the child the operation is much more difficult. If the breech fill the brim or is forced into the cavity, but little space is left for the operator's hand, and in this case the hand must be passed fully to the fundus uteri to reach the foot. No ordinary case of version involves passing the hand so high. Here it is essential that anæsthetics be given to the surgical degree, the rectum and bladder emptied, and the patient placed on her back.

The hand is gradually and gently passed by the breech that one being used whose palm will touch the abdomen of the child, until the foot be reached, preferably the anterior, when it is seized by the instep and drawn down so as to flex the leg on the thigh ; and in withdrawing the hand bring the foot out of the uterus and vulva. During the operation the uterus is steadied by the other hand or by an assistant. The case may now be left to follow the ordinary mechanism of breech cases. If inertia uteri be present, or resistance of the soft parts, or if prompt delivery be demanded in the interests of mother or child, we have attained, in the hold on the leg, a security for the further progress of the case.

The operation of extraction of the breech may be divided into three acts : Drawing the trunk through the pelvis, liberation of the arms, extraction of the head.

1. Traction on the leg should be carefully made, coincident with the pains, downward, and backward in the axis of the brim, external pressure being made by an assistant till the breech has fairly entered the cavity ; when the buttocks appear at the vulva, raise the leg toward the abdomen to release the posterior hip. When the breech is delivered, the cord should be looked after, the pulsations carefully watched, and if not feeble or interrupted, it should be placed at the sacro-iliac synchondrosis. The trunk should is kept warm by enveloping in a towel, and when traction is made, should be held lightly to afford opportunity for rotation of the shoulders.

2. Liberation of the arms. Liberation of the arms may be necessary if the pelvis be at all contracted, and also if traction on the trunk be too rapid or has not been accompanied by external pressure on the uterus.

The sacral one is most accessible. Lifting up the body of the child toward the pubes causes the sacral shoulder to descend, when with the fingers the arm is brought down over the front of the child. The pubic one is caused to descend by reversing the manœuvre ; carry the child's body backward over the coccyx. This brings down the pubic arms. Should this fail where the arms have been displaced backward, grasp the child's body above the hips and rotate it a little backward ; the arms are prevented by friction on the brim from following the trunk in its rotation ; the pubic arm is thrown across the breast, and now can easily be released.

The sacral arm is freed by the same manœuvre, but the rotation must be made in the opposite direction. Care should be taken that these axial turns be limited, or the head not following the trunk the spinal cord may be compressed by the rupture of the atlo-axoid articulation.

3. Extraction of the head. The mere friction of the child's body on the bed, as well as the loss of the expulsive power of the uterus, from its cavity being emptied of all but the head, and the subsidence of pain due to a protracted labor, demand the aid of the accoucheur. Besides, this is the stage of chief danger from compression of the cord.

Where the head has entered the pelvis and the only resistance to be overcome is that from the floor of the pelvis and the perineum, Smellie's method may be employed. Wrap the trunk of the child in a warm napkin and place it astride the arm ; pass the hand into the vagina, the middle and index fingers on the canine fossæ at the side of the nose, and at the same time make pressure upward by the fingers of the other other hand on the occiput. Now raise the trunk of the child over the abdomen of the mother; the head flexes around its suboccipital point, the face thereby being carried over the perineum.

[1] Science and Art of Midwifery, p. [illegible]

If sufficient flexion be not obtained the fingers may make pressure on the alveolar process of the lower jaw, making traction at the same time on the occiput. Where the occiput lies in the hollow of the sacrum, the chin should be flexed by the fingers, and with the back of the child on the operator's arm the traction should be made downward to the coccyx; the head flexes around, the occiput resting on the perineum and the face is born.

Smellie's method may be employed, the head being at the brim as recommended by Schroeder.

The Prague method, Scanzoni's, consists in seizing the feet with one hand while the fingers of the other hand are hooked over the shoulders. Traction is made downward in the axis of the brim simultaneously by both hands—external pressure on the head being made by an assistant. As soon as the head enters the cavity the extremities of the child are raised over the mother's abdomen, the hand on the shoulders acting as a fulcrum, the friction of the occiput on the pubes forces the face to descend into the hollow of the sacrum and sweep over the perineum.

In all cases of breech presentation the forceps should be at hand to extract the after-coming head. Care should be taken in its application that the cervix be not lacerated during its introduction. At the outlet it should be applied under the abdomen of the child, occipito-anterior, and the handles raised to flex the head when the child is reflected over the mother's abdomen. Where the occiput is posterior it is applied under the back of the child and draws the occiput into the hollow of the sacrum. The making of a gutter of the hand up to the face, to admit air, or passing a large-sized catheter into the mouth, will frequently allow the child to live when delay in extraction occurs.

PERMANGANATE OF POTASSIUM IN AMENORRHŒA.[1]

By C. E. BILLINGTON, M.D.,

NEW YORK.

The claims of permanganate of potassium to a high rank among emmenagogues are so recent, the testimony on which these claims are based is so convincing, and the questions which naturally arise as to its mode of action are so interesting that the topic seems a suitable one for the consideration of this Section.

The physical and chemical properties of this salt, its beautiful purple color, and its unpleasant taste, its ready solubility in water, its richness in oxygen, and the liberality with which it yields up that oxygen as oxygen and as ozone, and its resulting value as a deodorant and antiseptic, and in many important chemical and local therapeutical uses, are too well known to require detailed repetition.

On the skin and healthy mucous membranes it is innocuous; on surfaces denuded of epithelium it acts as a caustic. In the stomach it causes irritation and pain in doses of more than two or three grains, and not infrequently in those doses. The United States Dispensatory of 1883 says: "Internally, the medicine has been used in diphtheria, scarlatina, and various zymoses and in dyscrasia. It has even been claimed that in doses of half a grain to a grain it has cured pyæmia. It is plain that any moderate amounts of the permanganate must be decomposed by the organic matters of the mouth, œsophagus, and stomach before absorption, and there is no reason for believing that it is of any value as an internal medicine."

In the London *Lancet* of January 6, 1883, Drs. Ringer and Murrell announced that they had found permanganate of potassium to be a very valuable remedy in certain forms of amenorrhœa, this announcement being based on the results of their treatment of sixty-nine cases with this medicine alone, without accessory treatment.

The kinds of cases included in their enumeration are as follows: Their most striking results had been obtained in the case of young women between the ages of eighteen and twenty-five, who from some accidental or trivial cause, such as catching cold or getting wet, had missed once or twice after having been regular. "In these cases the administration of the drug for a few days before the expected period will bring on the flow almost to a certainty." In some instances the periods were brought on after the patient had ceased menstruating for over a year. In the case of country girls who had seen nothing for a month or two after coming to town, the treatment succeeded admirably. The permanganate often succeeded well after the failure of other emmenagogues.

In those cases in which the patient had menstruated only once or twice, and had then entirely ceased for some months, the menstrual discharge was re-established, and thenceforth proceeded normally. In girls of fifteen or sixteen, who had never menstruated at all, the result of the treatment was less certain; but even in these cases it not infrequently brought on the flow at once. In other instances in which the general health was bad, it failed at first, but succeeded after the patient had been sent into the country for a time, and in some others it failed altogether.

In cases of scanty menstruation, lasting only a single day or a few hours, the administration of the permanganate prolonged the flow.

In the case also of women between thirty-five and forty years of age who, as the result of many pregnancies and much suckling, had ceased to be regular, it succeeded almost equally well.

In the amenorrhœa of advanced phthisis it failed, but in some cases of arrested phthisis it proved successful in re-establishing regular menstruation.

In cases of chlorosis it not infrequently brought on the menstrual flow.

Drs. Ringer and Murrell administered the remedy either in the pharmacopœial solution or in pills, in doses of one or two grains three or four times a day, generally beginning with the smaller numbers, and gradually increasing to the larger, the latter doses sometimes succeeding when the former had failed.

They usually gave the permanganate only for the three or four days immediately preceding the expected period, but when it failed to produce the desired effect, the patient was directed to continue steadily taking it. Sometimes one or two doses succeeded, and in some cases it was taken continuously for nearly three months.

Their patients generally preferred the pills to the solution; the latter in some cases produced nausea and even vomiting.

One curious symptom frequently followed the taking of the permanganate in either form, viz., a persistent pain over the upper part of the sternum, "as if something had stuck fast there and would not go down."

Since the publication of this article occasional reports from other physicians have appeared in this country and in Europe of the results of their employment of this remedy, and while there have been in these reports some minor differences, there has been in all which I have seen a striking concurrence of testimony to the main fact of the therapeutical efficacy of the drug in the same kinds of cases as those just mentioned, or in similar ones.

Dr. Franklin H. Martin, of Chicago, in The Medical Record of September 29, 1883, besides strongly corroborating the above statements from the results of a considerable experience with the remedy, added that he had also found it efficacious in a case of amenorrhœa with phthisis of four months' duration, in a case of irregular menstruation accompanying prolonged digestive trouble, and in certain forms of menorrhagia and metrorrhagia, dependent on atony.

[1] Read before the Section on Materia Medica and Therapeutics of the New York Academy of Medicine, February 17, 1886.

Dr. Bartholow, in *The Medical News* of November 22, 1884, mentioned that Dr. S. M. Lvaff, a Russian physician, reports having obtained seven successful results with the permanganate in ten cases of amenorrhœa; and that another, Dr. A. V. Vargunin, has relieved by its use dysmenorrhœa with scanty menstruation and anæmia.

Dr. T. G. Thomas, in his address before the New York State Medical Association, November 10, 1884, said: "It is, I think, the best emmenagogue yet discovered."

Dr. E. J. Doering, of Chicago, published in *The Chicago Medical Journal and Examiner* of April 18, 1885, a list of fourteen carefully tabulated cases of amenorrhœa, showing eight successes and six failures. But in five of the six cases in which it failed it appears that the permanganate was given in doses of only one grain three or four times a day, while in the successful cases the doses were two, three, and four grains three or four times a day. Dr. Doering found that the larger doses produced, in every instance, epigastric and substernal pain.

Dr. P. M. Deas, of Exeter, England, reported in *The British Medical Journal* of April 18, 1885, his having employed the remedy with success in several cases of amenorrhœa associated with mental derangement, in which both conditions had been the result of mental shock or fright.

Including with the kinds of cases which are mentioned in the foregoing statements those which may properly be classed with them, it would appear that permanganate of potassium is quite generally applicable as a remedy to purely functional amenorrhœa, occurring in any stage of menstrual life, in diverse systemic conditions, and due to a great variety of causes, and also to some forms of dysmenorrhœa, menorrhagia, and metrorrhagia.

I have employed the remedy under consideration in four cases only—a number which, standing alone, would be insignificant, but taken in connection with the statements of Drs. Ringer and Murrell, have impressed me as illustrating in several respects their accuracy, and therefore as being worthy of brief relation. Those cases all occurred in my private practice.

Case I.—A young girl, of German parentage, eighteen years of age, was brought to me by her mother, in June, 1884, suffering from chlorosis greatly aggravated, if not originally caused, by malarial poisoning of a very obstinate type. Having previously been regular, she had failed to menstruate at the two periods next before I saw her. Among her other morbid symptoms was great gastric irritability. Various anti-malarial and tonic remedies were employed with but little benefit to her condition. She missed a third monthly period; and one week before a fourth one was due I prescribed the permanganate of potassium in solution, in two-grain doses three times a day. It caused her great gastric distress and nausea, and at times vomiting; but she persevered heroically in taking it, and, when the period arrived, menstruated normally. This was followed, however, by no improvement in her general health. She was sent to the seashore for six weeks, during which time she passed another period. She returned in somewhat improved health, and the permanganate was again prescribed. This time her stomach utterly refused to retain it, and its further employment was abandoned. Slow improvement and ultimate recovery of her health followed, but it was several months before her catamenia reappeared.

It will be observed in this case that the only menstruation which took place in eight or nine months was on the sole occasion when the patient had taken the permanganate; that this was not accompanied with improvement in the condition of toxæmia and chlorosis, and that the remedy was extremely irritating to the stomach.

Case II.—In November, 1884, I was called to see a school-girl of good family, aged about seventeen, who had previously been a type of perfect health and had menstruated regularly. I learned that while spending the previous August in the Catskills, she had received a wetting by being caught out in a shower. Since that occurrence her menstruation had taken place only in the form of a scanty, almost colorless, discharge. Her health had also been declining. She had suffered from frequent and persistent headaches, with coldness of the extremities, loss of appetite, shortness of breath, palpitations, etc. The bloom of her cheeks and lips was replaced by pallor, and the vivacity of her expression by languor and depression. Besides other remedies, indicated by her symptoms, I prescribed permanganate in two-grain capsules, to be taken three times a day, beginning one week before the time of her next menstrual period. She found it impossible to take the medicine on account of the gastric distress and nausea which it caused, and the menstruation which followed was of the same imperfect character as before. The following month, the condition of the stomach having in the meantime been improved by appropriate remedies, the patient was able to take the capsules without much difficulty, which was followed by a normal menstruation and a rapid return to perfect health.

Case III., which came under my care in October, 1884, was that of a young lady, aged about eighteen, surrounded by every circumstance promotive of happiness and health, but who from no discoverable cause had been for two months lapsing from her previous good health and menstrual regularity into a pitiable condition of anæmia and vital depression with amenorrhœa. The only explanation which I could arrive at was a possible hereditary tendency, as her mother, when she brought her to me, told me that she herself had been much troubled in the same way when at her age. The patient suffered from the worst symptoms of chlorosis—almost entire loss of appetite and digestive power, extreme feebleness, so that she had palpitation and shortness of breath on walking a short distance, occasional fainting, etc. For three months I prescribed for her a variety of ferruginous tonics, with quinine, nux vomica, arsenic, and aloes and myrrh, and enjoined outdoor exercise, amusements, nutritious food, and alcoholic stimulants. By January her appearance and her strength had somewhat improved, but still there was no menstruation. I then prescribed permanganate in two grain capsules, one three times a day. They produced no effect in January, but a repetition of the treatment in February was followed by a normal menstruation—the first in seven months.

Since that time she has taken the permanganate for one week before the date of every menstrual period, except during a three months' absence in the country last summer, when she did not take it, and did not menstruate at all, though her health was in other respects greatly improved. With this exception she has continued to menstruate about every alternate month, her health in other respects having been for some time fairly good.

In this case, while other remedies have failed to restore the menstrual function, the permanganate seems to have succeeded, but not invariably. I suspect that the reason of its not having succeeded completely is that the dose has been less than has been found necessary, in some cases, in order to produce the desired effect. I have directed this patient to take two grains, four times a day, before her next period—with what result remains to be seen.

Case IV. presented itself on Friday, January 29th, in the person of a young girl of rather anæmic appearance, aged sixteen. Her mother brought her to me because she suffered from palpitation and shortness of breath on making any exertion. She told me that her daughter had begun to menstruate one year before, since which time she had menstruated only four or five times. She had missed her period in December, and another one due on January 23d, or five days before I saw her. I prescribed twenty two-grain capsules of permanganate, to be taken, one three times a day, and requested her, when

she should have taken them, to report to me. On the following Monday morning she returned to ask me if she should continue to take the capsules, as they had produced the effect. She said that she had obtained them only on Saturday morning, and had taken three on that day, and that the flow had come on that night.

This patient also mentioned that she felt "as if something were sticking there"—pointing to the upper part of her sternum. The same curious symptom had also occurred on one occasion in the preceding case.

Mode of action.—Of the mode of action of this remedy Drs. Ringer and Murrell say "that the effects described are due to the manganese, and not to the potash in the salt, is shown by the fact that manganate of soda and binoxide of manganese are equally efficacious in the treatment of amenorrhœa. The manganate of soda was given in two-grain pills, two four times a day, and the binoxide in four-grain pills, one four times a day. It may be thought that the manganese acts by improving the condition of the blood, but this is not the case. The treatment succeeds equally well in the plethoric and in the anæmic. Given in cases of chlorosis, the permanganate not infrequently brings on the period without in any way improving the anæmia."

Dr. Bartholow, in the interesting and suggestive article on the action and uses of permanganate of potassium previously referred to, maintains that the chief, if not the only therapeutic effects of the salt are due to its oxygen, including in the term oxygen its nascent and peculiarly active form, ozone, this element being, in the light of modern researches, "a vital stimulant and an agent promoting the combustion process in all parts of the body." To the prime objection to this theory, viz., that the permanganate cannot act as such beyond the stomach on account of its speedy decomposition therein, Dr. Bartholow replies that there are reasons, which he has elsewhere given, for supposing that the diffusibility of this salt is so rapid that it has some action on the blood. As an example of such reasons, he cites the local use of the permanganate in the bites of venomous serpents, in which the poison is destroyed, notwithstanding the organic matter in which it is inclosed.

In considering this theory it would seem pertinent to inquire, Has oxygen or has ozone, in any of the other forms or modes in which it has been administered, been found to have any such prompt and special action upon the menstrual function as that which the permanganate of potassium has been shown in some cases to exert? If any evidence to that effect exists I have not met with it.

In the absence of such evidence this theory would require that the permanganate of potassium should bring on the catamenia by improving the condition of the blood and acting as a general invigorant; but we have seen that this is not the fact, since in some cases it effects the one object without at all accomplishing the other, and when it does both, the former result is often remarkably speedy, while the latter must be comparatively slow and gradual, so that either must be regarded as independent of, and distinct from, the other.

In regard to the question, whether the permanganate or manganese in other forms does act as a general tonic and blood-restorer in anæmia and chlorosis, the testimony is, as on so many others in therapeutics, conflicting. Ringer, for instance, in the latest edition of his "Therapeutics," denies that it has that action. Other competent observers, among whom, as will presently appear, is an eminently trustworthy one, answer the question in the affirmative.

It appears to be an obstinate chemical fact that permanganate of potassium, on account of the rapidity with which it is decomposed by organic matters, cannot possibly act as such beyond the stomach. This is positively stated in the latest edition of Ringer's Therapeutics. In the paper of Dr. Doering, to which reference has been made, is included an opinion of Professor N. Gray Bartlett, a well-known chemist of Chicago, to the same effect. Professor Bartlett adds that in all probability the manganese of the permanganate separates in the stomach in the form of the hydrated manganese dioxide. If this be true, it follows that for all therapeutical purposes outside of the stomach itself the internal administration of the permanganate of potassium is simply one mode of the administration of binoxide of manganese.
